STRUCTURE AND FUNCTION OF THE SKIN

Layers of the Skin

The skin is formed of two major layers: (1) a superficial or outer layer of **epidermis,** and (2) a deeper layer of **dermis** (the true skin) (Figure 46-1). The subcutaneous layer **(hypodermis)** is the lowest lying layer of connective tissue that contains macrophages, fibroblasts, fat cells, nerves, fine muscles, blood vessels, lymphatics, and hair follicle roots. Each skin layer contains cells that represent progressive stages of skin cell differentiation and function as the skin grows. These are summarized in Table 46-1.

Epidermis

The **epidermis** is a defensive barrier that continually renews itself by shedding the superficial layer of **stratum corneum.** It is formed primarily of keratinocytes embedded in a lipid matrix. These cells are named for the substances they produce. **Keratinocytes** produce **keratin,** a scleroprotein that provides protection from mechanical stress. Keratin is the main constituent of skin, hair, and nail cells. The thickness of the epidermis varies from 0.3 mm on the eyelids to 1.5 mm on the palms of the hands and soles of the feet. New cells (keratinocytes) formed in the **basal layer (stratum basale)** move upward and differentiate, forming

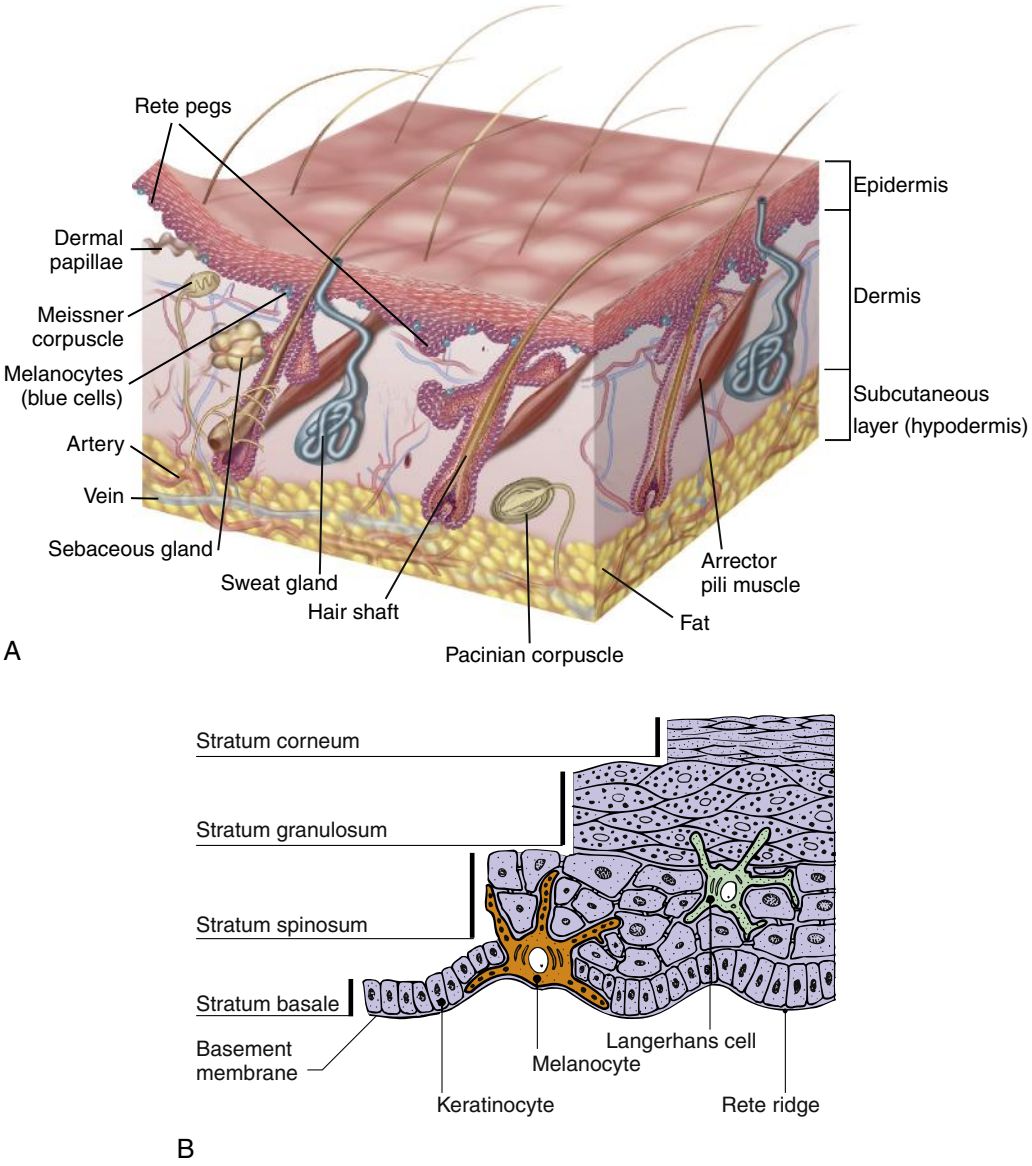

FIGURE 46-1 Structure of the Skin. **A,** Cross section showing major skin structures. **B,** Layers of the epidermis. (**A** from Kumar V et al: *Robbins & Cotran pathologic basis of disease,* ed 8, St Louis, 2009, Saunders; **B** from Gawkrodger D, Ardern-Jones MR: *Dermatology,* ed 5, Philadelphia, 2012, Churchill Livingstone.)

the **spinous layer (stratum spinosum).** Together they form the **germinative layer (stratum germinativum)** and ensure continual renewal of the skin. The cells enlarge and then become flattened, stacked, and cornified (stratum corneum) as they ascend to the skin surface. Cornification, or keratinization, prevents dehydration of deeper skin layers and loss of body water. The average turnover of the epidermis is about 30 days.

The epidermis has three additional types of cells that facilitate its functional characteristics: melanocytes, Langerhans cells, and Merkel cells. The **melanocytes** are usually located near the base of the epidermis. They synthesize and secrete the pigment melanin with exposure to UV light in response to melanocyte-stimulating hormone (MSH). Melanin in the epidermis provides a shield against UV radiation and determines skin color. **Vitiligo** is an autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin (see "Patch" in Table 44-3, p. 1547). **Langerhans cells** migrate to the epidermis from the bone marrow. Langerhans cells (a type of dendritic cell) and dermal dendritic cells initiate an immune response by presenting processed antigen to T cells, thus providing a defense against environmental antigens.[1] **Merkel cells** are associated with touch receptors and function as slowly adapting mechanoreceptors when stimulated by deformation of the epidermis.

Dermis

The **dermis** is 1 to 4 mm thick and is composed of three types of connective tissue: (1) collagen, (2) elastin and reticulin, and (3) a gel-like ground substance. The haphazard arrangement of connective tissue allows the skin to be mobile and to stretch and contract with body movement. Hair follicles, sebaceous glands, sweat glands, blood vessels, lymphatic vessels, and nerves are

TABLE 46-1 LAYERS OF THE SKIN

LAYER	CELL TYPES	CHARACTERISTICS
Epidermis		Most important layer of skin; normally very thin (0.12 mm) but can thicken and form corns or calluses with constant pressure or friction; includes rete pegs that extend into papillary layer of dermis
Stratum corneum	Keratinocytes	Tough superficial sheets of cornified cells
Stratum lucidum	Keratinocytes	Clear layers of cells containing eleidin, which becomes keratin as cells move up to the corneum layer; *found only in palmoplantar skin*
Stratum granulosum	Keratinocytes	Lose their nuclei Keratohyalin gives a granular appearance to this layer
Stratum spinosum	Keratinocytes	Polygonal-shaped with spinous processes projecting between adjacent keratinocytes
	Langerhans cells	Cells with dendritic processes and immune function
Stratum basale (germinativum)	Keratinocytes	Basal layer where keratinocytes divide and move upward to replace cells shed from the surface
	Melanocytes	Originate in neural crest and migrate to stratum basale and produce melanin
	Merkel cells	The function of Merkel cells is not clearly known—have role in light touch
Dermis	Macrophages	Irregular connective tissue layer with rich blood, lymphatic, and nerve supply; contains sensory receptors and sweat glands (apocrine, eccrine, sebaceous); macrophages (phagocytic and important for wound healing) and mast cells (release histamine) have immune functions (see Chapter 7)
Papillary layer (thin)	Mast cells	
Reticular layer (thick)	Histiocytes	Histiocytes are wandering macrophages that collect pigments and inflammatory debris
	Fibroblasts	Generate connective tissue; imported for wound healing
Subcutaneous (Hypodermis)		Subcutaneous tissue or superficial fascia of varying thickness that connects the overlying dermis to underlying muscle; contains macrophages, fibroblasts, fat cells, nerves, blood vessels, lymphatics, and hair follicle roots

contained in the dermis. The conelike projections of the papillary dermis interface with the epidermis. The papillae provide texture to the surface of the skin by forming *rete pegs.*

The cells of the dermis include fibroblasts, mast cells, and macrophages. Fibroblasts secrete the connective tissue matrix and collagen. Mast cells release histamine and play a role in hypersensitivity reactions in the skin. Macrophages are phagocytic and participate in immune responses. Histiocytes are macrophages that reside in loose connective tissue and phagocytize pigments and the debris of inflammation.

Subcutaneous Layer

The third layer of the skin is subcutaneous tissue and consists of fat cells or adipocytes. The lobules are separated by fibrous walls (septa) of collagen and large blood vessels. Dermal collagen is continuous with the collagen found in the subcutaneous tissue.

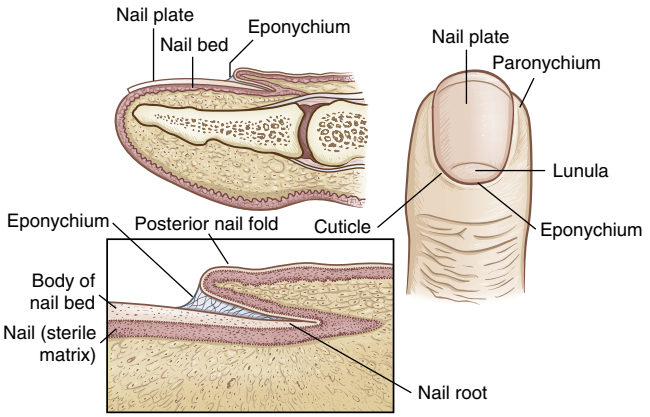

FIGURE 46-2 Structures of the Nail. (Redrawn from Thompson JM et al: *Mosby's clinical nursing,* ed 5, St Louis, 2002, Mosby.)

Dermal Appendages

The **dermal appendages** include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands. The **nails** are protective keratinized plates composed of four structural units: (1) the proximal nail fold, (2) the matrix from which the nail grows, (3) the hyponychium (nail bed), and (4) the nail plate (Figure 46-2). Nail growth is continuous throughout life at a rate of 1 mm or less per day.

Hair follicles and sebaceous glands are integrated units (see Figure 46-1). Hair color, density, grain, and pattern of distribution have considerable variability and depend on age, gender, and race. **Hair follicles** arise from the matrix (or bulb) located deep in the dermis. They extend from the dermis at an angle and have an erector pili muscle attached near the mid-dermis that straightens the follicle when contracted, causing the hair to stand up. Hair growth begins in the bulb, with cellular differentiation of stem cells occurring as the hair progresses up the follicle.[2] Hair color is determined by melanin-secreting follicular melanocytes. Hair is fully hardened, or cornified, by the time it emerges at the skin surface. Hair growth is cyclic, with periods of growth and rest that vary over different body surfaces.

The **sebaceous glands** open onto the surface of the skin through a canal. They are found in greatest numbers on the face, chest, and back; modified glands are found on the eyelids, lips, nipple, glans penis, and prepuce. Sebaceous glands secrete sebum, composed primarily of lipids, that oils the skin and hair and prevents drying. Growth of sebaceous glands is stimulated by androgens, and their enlargement is one of the early signs of puberty.

The **eccrine sweat glands** are distributed over the body, with the greatest numbers in the palms of the hands, soles of the feet, and forehead. These secretions are important in thermoregulation and cooling of the body through evaporation. The **apocrine sweat glands** are fewer in number and are located in the axillae, scalp, face, abdomen, and genital area and have very limited proven function.

TABLE 46-2 SUMMARY OF SKIN DIAGNOSTIC PROCEDURES

TEST	PURPOSE
Dermoscopy	Magnified illumination of the skin using a liquid medium and transparent plate to examine skin lesions
Skin biopsy	Histologic examination of tissue to determine differential diagnosis of cellular structure (i.e., benign growths vs. carcinoma, chronic infections, blistering diseases, and vasculitis)
Microscopic immunofluorescence	Identification of antibodies, immunoglobulins, and complement components for diseases such as pemphigus, vasculitis, and discoid lupus erythematosus using fluorescent light on slide-mounted biopsy specimens
Gram stain	Differentiation of gram-positive from gram-negative bacteria according to stain absorption
Culture	Identification of chronic bacterial and fungal infections by incubating skin specimens in culture media
Wood lamp examination	Examination of skin or hair to identify fungus that fluoresces bright yellow-green under ultraviolet light
Patch and scratch tests	Application of suspected allergens to skin by patch or scratch for evaluation of immune system responses to known allergens and evaluation of cell-mediated immune function (*Candida albicans*, skin fungus, chemicals, aeroallergens, and foods)
Skin scrapings	Application of potassium hydroxide and low heat to skin scrapings on a glass slide to identify dermatophytes and *C. albicans*
Side lighting	Indirect lighting of the skin using light to the side of the lesions to evaluate patterns of depression and elevation of skin lesions
Diascopy	Use of glass or clear plastic pressed on the skin to differentiate erythema caused by dilated capillaries (blanching) from extravasation of blood (no blanching)
Tzanck smear	A microscopic examination of cellular material from skin lesions to help diagnose vesicular diseases, including herpes simplex virus and varicella-zoster virus

Blood Supply and Innervation

The blood supply to the skin is limited to the **papillary capillaries,** or plexus, of the dermis. These capillary loops arise from a subpapillary plexus that is supplied by a deeper horizontal cutaneous arterial plexus. Branches from the deep plexus supply hair follicles and sweat glands. A subpapillary network of veins drains the capillary loops. Arteriovenous anastomoses in the dermis facilitate the regulation of body temperature. Heat loss can be regulated by varying blood flow through the skin by opening and closing the arteriovenous anastomoses in conjunction with evaporative heat loss of sweat. The sympathetic nervous system regulates vasoconstriction and vasodilation through α-adrenergic receptors. The lymphatic vessels arise in the papillary dermis and drain into larger subcutaneous trunks, removing cells, proteins, and immunologic mediators.

AGING AND SKIN INTEGRITY

Many age-associated changes in the skin are generalized and readily observable. Genetics and cumulative environmental factors, including UV radiation from sun exposure (photoaging), inflammatory responses, tobacco smoke, and gravity contribute to cutaneous changes with aging.[3,4] Structurally the skin becomes thinner, less elastic, drier, and wrinkled with a change in pigmentation. The cellular alterations contributing to the changes include a flattening of the dermoepidermal junction with a shortening and decrease in the number of capillary loops. There are fewer melanocytes, resulting in decreased protection against UV radiation. A significant decrease in the number of Langerhans cells reduces the skin's immune response with aging. The thickness of the dermis also decreases and accounts for the translucent, paper-thin quality of the skin. Loss of the rete pegs gives the skin a smooth, shiny appearance.[5]

The decreased vasculature and lymphatic drainage contribute to loss of barrier protection and the atrophy of eccrine, apocrine, and sebaceous glands, all of which promote dry skin. Loss of elastin fibers is associated with wrinkling. Collagen fibers become fragmented, and fibroblasts decrease in number, resulting in a decreased ability of the skin to stretch and regain shape. Decreased cell proliferation, diminished blood supply, and depressed immune responses also delay wound healing in aging skin. Changes in hair color and distribution also occur. Graying is caused by loss of melanocytes from hair bulbs, and thinning occurs from a gradual decline in the number of hair follicles and growth of finer hair.[6]

Epidermal cells change shape, and the barrier function of the stratum corneum is reduced. There is increased permeability and decreased clearance of toxic oxidative substances from the dermis. The accumulation of such substances is related to decreased vascularity and can cause skin irritation. Temperature regulation is compromised in older adults, with an increased risk for heat stroke and hypothermia. Loss of cutaneous vasomotion and subcutaneous fat, reduced vascularity, and decreased eccrine sweat production are contributing factors.[7] The pressure and touch receptors and free nerve endings decrease in number and reduce sensory perception. With aging many of the protective functions of the skin decrease, whereas the likelihood of infection and delay in wound healing increase.[8]

Tests of Skin Function

Diagnostic evaluations of skin disorders often can be completed by gathering historical information, performing a physical examination, and observing the distribution and characteristics of the presenting lesions. Additional diagnostic studies are summarized in Table 46-2.

Clinical Manifestations of Skin Dysfunction

Lesions

Lesions of the skin are readily observable and easily assessed for distribution and structure. Identification of the morphologic structure, including a differentiation between the primary and secondary lesions, and the general appearance of the skin is critical. The physical exam, in combination with a thorough health history, is essential to identify the underlying pathophysiology. Table 46-3 describes and illustrates the primary lesions of the skin and Table 46-4 describes and illustrates the

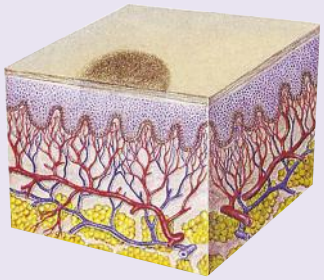
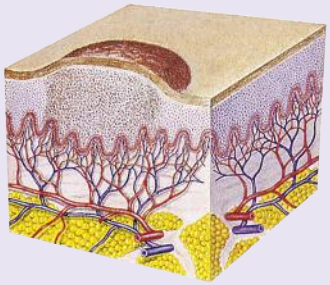
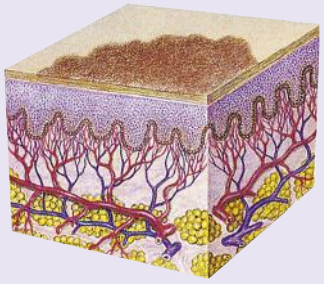
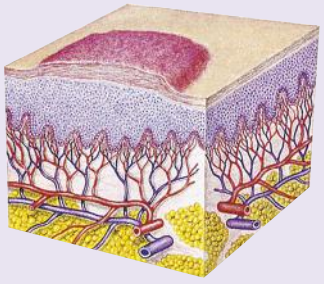
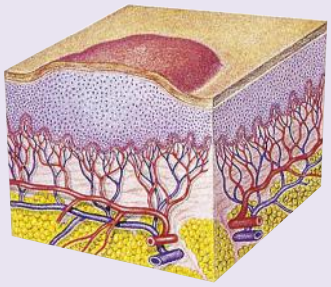
TABLE 46-3 PRIMARY SKIN LESIONS

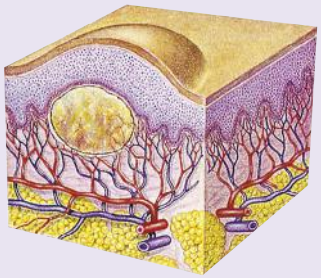


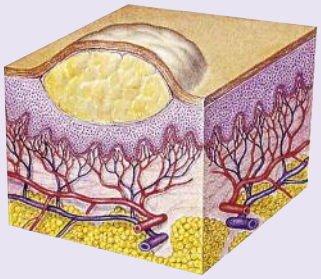


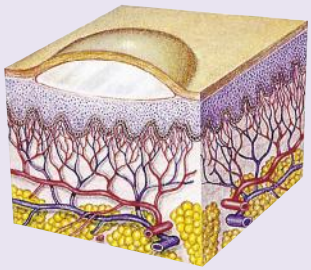


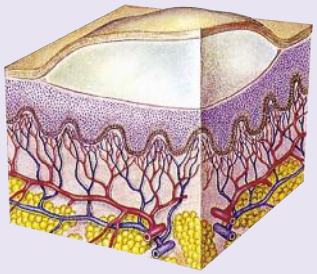


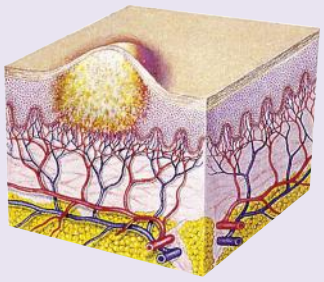


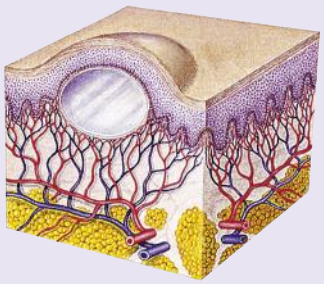


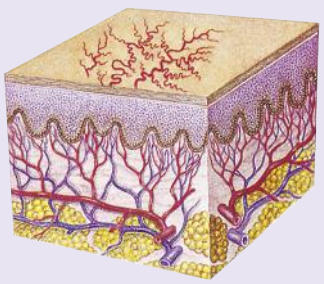








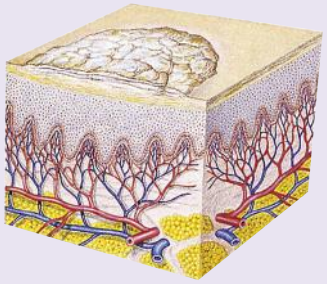


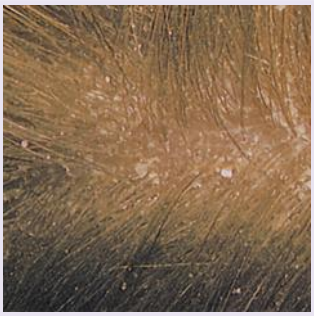


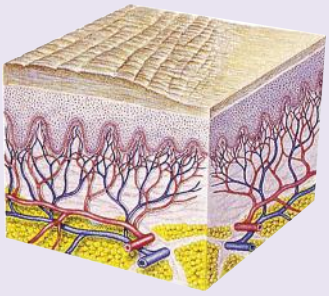
LESIONS	EXAMPLES		
Macule A flat, circumscribed area that is a change in the color of the skin; less than 1 cm in diameter	Freckles, flat moles (nevi), petechiae, measles, scarlet fever		 Macules[a]
Papule An elevated, firm, circumscribed area less than 1 cm in diameter	Wart (verruca), elevated moles, lichen planus, fibroma, insect bite		 Lichen planus[b]
Patch A flat, nonpalpable, irregular-shaped macule more than 1 cm in diameter	Vitiligo, port-wine stains, mongolian spots, café-au-lait spots		 Vitiligo[c]
Plaque Elevated, firm, and rough lesion with flat top surface greater than 1 cm in diameter	Psoriasis, seborrheic and actinic keratoses		 Plaque[d]

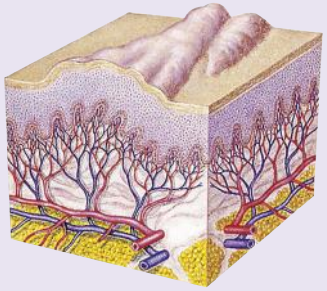
TABLE 46-3 PRIMARY SKIN LESIONS—cont'd

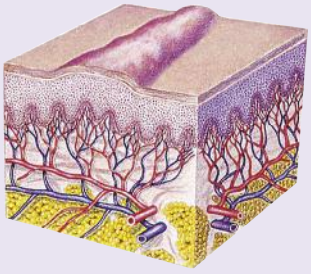
LESIONS	EXAMPLES		
Wheal Elevated, irregular-shaped area of cutaneous edema; solid, transient; variable diameter	Insect bites, urticaria, allergic reaction		 Wheal[e]
Nodule Elevated, firm, circumscribed lesion; deeper in dermis than a papule; 1-2 cm in diameter	Erythema nodosum, lipomas		 Lipoma[f]
Tumor Elevated, solid lesion; may be clearly demarcated; deeper in dermis; greater than 2 cm in diameter	Neoplasms, benign tumor, lipoma, neurofibroma, hemangioma		 Neurofibroma[f]
Vesicle Elevated, circumscribed, superficial, does not extend into dermis; filled with serous fluid; less than 1 cm in diameter	Varicella (chickenpox), herpes zoster (shingles), herpes simplex		 Vesicles[g]











Continued

TABLE 46-3 PRIMARY SKIN LESIONS—cont'd

LESIONS	EXAMPLES		
Bulla			
Vesicle greater than 1 cm in diameter	Blister, pemphigus vulgaris		 Bullae[h]
Pustule			
Elevated, superficial lesion; similar to a vesicle but filled with purulent fluid	Impetigo, acne		 Acne[c]
Cyst			
Elevated, circumscribed, encapsulated lesion; in dermis or subcutaneous layer; filled with liquid or semisolid material	Sebaceous cyst, cystic acne		 Sebaceous cyst[c]
Telangiectasia			
Fine (0.5-1.0 mm), irregular red lines produced by capillary dilation; can be associated with acne rosacea (face), venous hypertension (spider veins in legs), systemic sclerosis, or developmental abnormalities (port-wine birthmarks)	Telangiectasia in rosacea		 Telangiectasia[e]

TABLE 46-5 SPECIAL SKIN LESIONS

TYPE	CLINICAL MANIFESTATIONS
Comedone	A plug of sebaceous and keratin material lodged in the opening of a hair follicle; an open comedone has a dilated orifice (blackhead), and a closed comedone has a narrow opening (whitehead)
Burrow	A narrow, raised, irregular channel caused by a parasite
Petechiae	A circumscribed area of blood less than 0.5 cm in diameter
Purpura	A circumscribed area of blood greater than 0.5 cm in diameter

secondary lesions of the skin. Special skin lesions are described in Table 46-5.

Pressure Ulcers. Pressure ulcers are ischemic ulcers resulting from unrelieved pressure, shearing forces, friction, and moisture. Pressure that consistently interrupts arterial and venous blood flow to and from the skin or deeper tissue is the most significant cause.[9] The term *decubitus ulcer* refers to an ulcer or pressure sore that results when an individual lies or sits in one position for a long time. The more general terms of *pressure sore* or *ulcer* are used here. Risk factors for pressure ulcers are summarized in Box 46-1.

Most individuals with darkly pigmented skin are at greater risk for developing pressure ulcers because early signs of skin damage may not be clearly visible.[10] Pressure sores usually develop over bony prominences: the sacrum, heels, ischia, and greater trochanters are the most common sites. Continuous pressure on tissue between the bony prominence and a resistant outside surface distort capillaries and occlude the blood flow and oxygen supply. Several scales are available for predicting pressure sore risk; the Braden Scale is one of those most frequently used.[11-13] One classification of pressure ulcer grades or stages is summarized as follows[14]:

I. Nonblanchable erythema of intact skin usually over bony prominence; darkly pigmented skin may not have visible blanching
II. Partial-thickness skin loss (erosion or blistering) involving epidermis or dermis presenting as a shallow open ulcer with a red-pink wound bed, without slough
III. Full-thickness skin loss involving damage or necrosis of subcutaneous tissue that may extend to, but not through, underlying fascia
IV. Full-thickness tissue loss with exposure of muscle, bone, or supporting structures (tendons or joint capsules); can include undermining and tunneling

Suspected deep tissue injury is localized in an area of purple or maroon discolored intact skin or blood-filled blister caused by underlying soft tissue damage from pressure and/or shear.

Unstageable is full-thickness tissue loss with base of ulcer covered by slough or eschar, or both, in the wound bed.

Superficial damage results in a layer of dead tissue that appears as a blister, erosion, or nonblanchable red/darkened skin or as a reddish blue discoloration when there is deeper tissue damage. Superficial sores are more common on the sacrum as a result of shearing or friction forces (forces parallel to the skin). Deep sores develop closer to the bone as a result of tissue distortion and vascular occlusion from pressure that is perpendicular to the tissue (over the heels, trochanter, and ischia) (Figure 46-3).

The primary goal for those at risk for pressure ulcers is prevention, including frequent skin assessment with repositioning and turning; use of pressure reduction surfaces and specialty beds; elimination of incontinence, moisture, and drainage; and maintenance of fluid, protein, and caloric intakes.[15,16]

BOX 46-1 PRESSURE ULCER RISK FACTORS

Prolonged Pressure/Immobilization

Lying in bed or sitting in chair or wheelchair without changing position or relieving pressure over an extended period
- Lying for hours on hard x-ray and operating tables
- Neurologic disorders (coma, spinal cord injuries, cognitive impairment, or cerebrovascular disease)
- Fractures or contractures
- Debilitation: elderly persons in hospitals and nursing homes
- Pain
- Sedation

Shearing forces
- Turning by dragging on coarse bed sheets

Disease/Tissue Factors

Impaired perfusion; ischemia
Fecal or urinary incontinence; prolonged exposure to moisture
Malnutrition, dehydration
Chronic diseases accompanied by anemia, edema, renal failure, malnutrition, peripheral vascular disease, or sepsis
Previous history of pressure ulcers

Additional Risk Factors for the Critically Ill

Norepinephrine infusion
Acute Physiology and Chronic Health Evaluation (APACHE II) score
Anemia
Age greater than 40 years
Multiple organ system disease or comorbid complications
Length of hospital stay

Data from Alderden J et al: *Crit Care Nurse* 31(4):30–43, 2011; Coleman S et al: *Int J Nurs Stud* 50(7):974–1003, 2013; Cowan LJ et al: *Wound Repair Regen* 20(2):137–148, 2012; Guihan M, Bombardier CH: *J Spinal Cord Med* 35(4):240–250, 2012; Jaul E: *Drugs Aging* 27(4):311–325, 2010; Thomas DR: *J Am Med Dir Assoc* 11(6):397–405, 2010; White-Chu EF et al: *Clin Geriatr Med* 27(2):241–258, 2011.

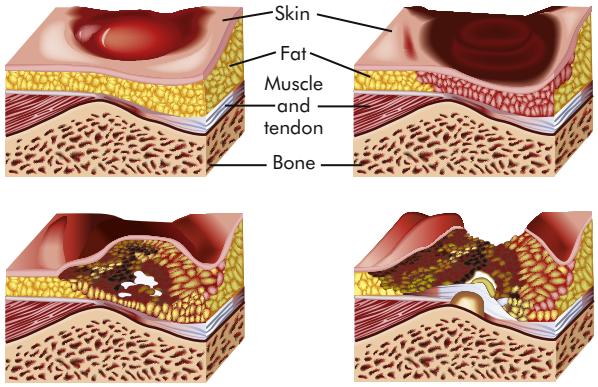

FIGURE 46-3 Progression of Decubitus Ulcer. Sustained pressure over a bony prominence compresses the tissue and reduces blood flow, resulting in progressive ischemia and necrosis of tissue.

Superficial ulcers should be covered with flat, moisture-retaining dressings that cannot wrinkle and cause increased pressure or friction; multiple options are available.[17] Successful healing requires continued adequate relief of pressure; débridement of dead tissue; use of specialty wound care products (dressings, foams, gels, cleansers); and repair with skin flaps for large, deep ulcers. Negative pressure wound healing is a useful technology in the treatment of stage III/IV pressure ulcers.[18,19] Infection requires treatment with antibiotics and pain should be controlled.[20] Randomized controlled trials are needed to determine the best methods for treating pressure ulcers.[21,22]

Keloids and Hypertrophic Scars. **Keloids** are rounded, firm, elevated scars with irregular clawlike margins that extend beyond the original site of injury. **Hypertrophic scars** are elevated erythematous fibrous lesions that do not expand beyond the border of injury. Both lesions are genetically influenced and caused by abnormal wound healing with excessive fibroblast activity and collagen formation during dermal connective tissue repair.[23,24] A familial tendency for keloid formation has been found and both autosomal recessive and autosomal dominant inheritance patterns have been reported.[25] Genes regulating fibroblasts may be up- or down-regulated in keloid tissue.[26]

Keloids are most common in darkly pigmented skin types and burn scars (see Chapter 48). Excessive or poorly aligned tension on a wound, introduction of foreign material into the skin, and the occurrence of certain types of trauma (e.g., burns) are provocative factors. At risk are the shoulders, back, chin, ears, and lower legs. Keloids can appear within weeks to months after a stable scar has formed. Individuals 10 to 30 years of age develop lesions much more commonly than do children before puberty or older adults. Hypertrophic scars usually regress within a year.

The amount of type III collagen is increased with keloids. The increased synthesis of collagen is associated with interleukin-6 (IL-6) signaling and dermal fibroblasts that have high metabolic and mitotic rates. There is aberrant expression of transforming growth factor-beta (TGF-β) and platelet-derived growth factor (PDGF).[27]

Myofibroblasts, cells with characteristics of fibroblasts and smooth muscle cells, are the principal cells in keloids. Collagenase activity in keloids is normal or increased, but the collagen may be protected from degradation by **proteoglycan,** a glycoprotein present in connective tissue that serves as a binding (cementing) material, and by specific inhibitors of proteolytic enzymes.[28] Keloids first appear as pink or red, firm, well-defined rubbery plaques that persist for several months after trauma. Later, uncontrolled overgrowth causes extension beyond the site of the original wound and the tumor becomes smoother, irregularly shaped, hyperpigmented, and harder with **clawlike prolongations** (Figure 46-4).

Keloids are the most extreme example of cutaneous scarring and the most difficult to treat. Preventive measures such as avoidance of unnecessary elective surgeries, recognition of familial tendency, and early detection are of paramount

FIGURE 46-4 Keloid. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

importance. Standard management of keloids and hypertrophic scars includes intralesional corticosteroids, cryotherapy, radiotherapy, and surgical/laser procedures whereas intralesional injections of interferon, bleomycin, and 5-fluorouracil (5-FU) are emerging treatments.[29] There remains a need for research to improve treatment outcome.[30,31]

Pruritus

Pruritus, or itching, is the most common symptom associated with many primary skin disorders, such as eczema, psoriasis, or lice infestations, or it can be a manifestation of systemic disease (e.g., xerosis, chronic renal failure, cholestatic liver disease, thyroid disorders, iron deficiency, neuropathies, or malignancy) or drug reactions. Pruritus may be acute (e.g., mosquito bite) or chronic, and may be localized or generalized and migratory.

Multiple stimuli can produce itching and there is interaction between itch and pain sensations. Peripheral pruritogenic (itch) mediators include histamine, neuropeptides, serotonin, prostaglandins, bradykinin, substance P, opioids, acetylcholine, interleukin-31, and nerve growth factor. Itch sensation is thought to be carried by specific unmyelinated C nerve fibers and thinly myelinated Aδ nerve fibers. Specific spinal pathways carry itch sensations through the spinal cord to the brain.[32] These nerve fibers also may interact with dermal eosinophils, lymphocytes, and mast cells.[33]

Central nervous system mechanisms also can modulate itching, which is less perceptible when the mind is distracted by other stimuli. How the central nervous system influences the itch sensation is unclear. *Neuropathic itch* (itch without pruritogenic stimuli) is related to pathology along an afferent pathway (i.e., postherpetic neuropathy).[34] *Psychogenic itch* is associated with psychologic disorders (e.g., depression and obsessive-compulsive disorder).[35]

Chronic itching is an unpleasant sensation that may or may not be relieved by scratching—often done so intensely that trauma to the skin occurs, resulting in infection, skin thickening (lichenification), and scarring. Both central and peripheral sensitization occurs.[35] Some individuals become so distraught with the constant irritation that they apply heat and/or ice with enough intensity and duration to produce skin injury. Management of itching is challenging and depends on the cause; the primary condition must be treated. Both topical and systemic therapies are used.[36,37]

FIGURE 46-5 Poison Ivy. A, Poison ivy on knee. **B,** Poison ivy dermatitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

DISORDERS OF THE SKIN

Disruptions in skin integrity may be precipitated by trauma, abnormal cellular function, infection and inflammation, and systemic diseases. Many skin disorders are benign and self-limiting, whereas others are severe and life threatening.

Inflammatory Disorders

The most common inflammatory disorder of the skin is **eczema,** or dermatitis. Eczema and dermatitis are general terms that describe a particular type of inflammatory response in the skin—the terms can be used interchangeably. Eczematous disorders are generally characterized by pruritus, lesions with indistinct borders, and epidermal changes. These lesions either can appear as erythema, papules, or scales or can present in an acute, subacute, or chronic phase. Edema, serous discharge, and crusting occur with continued irritation and scratching. In chronic eczema the skin becomes thickened, leathery, and hyperpigmented from recurrent irritation and scratching. The location of eczema is related to the underlying cause. Eczematous inflammations need to be differentiated from other dermatoses, particularly psoriasis.

Allergic Contact Dermatitis

Allergic contact dermatitis is a common form of T-cell–mediated or delayed hypersensitivity (type IV).[38] (See Chapter 9 for various types of allergic responses.) Genetic susceptibility involves several genes including loss-of-function mutations in the gene encoding the epidermal protein filaggrin.[39] Allergens (e.g., microorganisms, chemicals, foreign proteins, drugs, metals, latex) can form the sensitizing antigen; contact with poison ivy is a common example (Figure 46-5). The response is a

reaction to irritants with release of cytokines, chemokines, and cytotoxins from keratinocytes, dendritic cells (Langerhans cells), and natural killer cells. When the allergen comes into contact with the skin the allergen is bound to a carrier protein, forming a hapten-specific sensitizing antigen. Langerhans cells process the antigen and carry it to T cells that then become sensitized to the antigen, releasing cytokines and chemokines and leading to leukocyte infiltration and inflammation.[40] Latex allergy can be either a type IV hypersensitivity reaction to chemicals used in latex rubber processing or a type I immediate hypersensitivity reaction with IgE antibodies formed in response to latex rubber protein.[41]

In delayed hypersensitivity, several hours pass before an immunologic response is apparent. The T cells play an important role because they differentiate and secrete lymphokines that affect macrophage movement and aggregation, coagulation, and other inflammatory responses (see Chapter 9). Sensitization usually develops with first exposure to the antigen, and symptoms of dermatitis occur with reexposure.

The manifestations of allergic contact dermatitis include erythema and swelling with pruritic (itching) vesicular lesions in the areas of allergen contact. The pattern of distribution provides clues to the source of the antigen (e.g., hands exposed to chemical solutions or boundaries from rings and bracelets). Patch tests with specific antigens may assist with diagnosis. Removal of the allergen is necessary for resolution of the inflammatory response and tissue repair. Topical or systemic steroids, as well as other symptomatic treatment, may be required depending on the severity of the lesion.[42]

Irritant Contact Dermatitis

Irritant contact dermatitis is a common nonimmunologically-mediated inflammation of the skin. The intensity of the inflammation is related to the concentration of the irritant, exposure time, disruption of the skin barrier, and age.[43] Irritation can occur from almost anything, especially if the epidermal barrier is compromised in any way (Box 46-2). The skin lesions are similar in appearance to allergic contact dermatitis. Removing the source of irritation and using topical agents (i.e., corticosteroids and petroleum-based emollients) and nonirritating soaps constitute effective treatment.

Atopic Dermatitis

Atopic dermatitis (allergic dermatitis) is more common in infancy and childhood; however, some individuals are affected throughout life. See Chapter 47 for details.[44]

Stasis Dermatitis

Stasis dermatitis usually occurs on the legs as a result of venous stasis and edema. The disorder is associated with varicosities (incompetent venous valves), phlebitis, and vascular trauma. Pooling of venous blood traps leukocytes that may release proteolytic enzymes. Increased venous pressure widens interendothelial pores with deposition of red blood cells, fibrin, and other macromolecules, making them unavailable for repair and promoting inflammation.[45] Edema evolves to erythema and pruritus with progression to scaling, petechiae, and hyperpigmentation.

BOX 46-2 SUBSTANCES KNOWN TO CAUSE CONTACT DERMATITIS*

- Alkalis
  - Soaps
  - Detergents
  - Ammonia preparations
  - Lye
  - Drainpipe cleaners
  - Toilet bowl cleaners
  - Oven cleaners
- Acids
- Metal salts
  - Cyanides of calcium, copper, mercury, nickel, silver, zinc
  - Chlorides of calcium and zinc
- Bromine, chlorine, iodine, fluorine
- Insecticides
- Herbicides
- Dusts of lime, zinc, arsenic
- Dyes and fragrances
- Wood dust from teak, cinchona bark, quinine, pyrethrum
- Tobacco dust from cigars
- Explosive powders
- Hydrocarbons
  - Crude petroleum, lubricating oil, cutting oil
  - Paraffins, mineral oils
  - Asphalt, other tar products
- Soot, peat
- Preservatives

*For chemicals that cause occupational allergic contact dermatitis see National Library of Medicine: Haz-map Table 1: Chemicals that cause occupational allergic contact dermatitis, Bethesda, MD, last updated April 2013. Available at www.hax-map.com/allergic.htm.

FIGURE 46-6 Stasis Ulcer. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Progressive lesions become ulcerated (stasis ulcers), particularly around the ankles and tibia (Figure 46-6).

Treatment includes elevating the legs as often as possible, refraining from wearing tight clothes around the legs, and avoiding standing for long periods. Defined infections are treated with antibiotics. Chronic lesions with ulceration are treated with moist dressings, external compression garments, and vein ablation surgery.[46]

FIGURE 46-7 Seborrheic Dermatitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

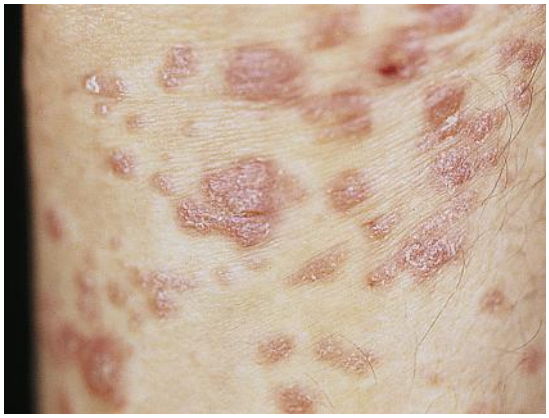

FIGURE 46-8 Psoriasis. Typical oval plaques with well-defined borders and silvery scale. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Seborrheic Dermatitis

Seborrheic dermatitis is a common chronic inflammation of the skin involving the scalp, eyebrows, eyelids, ear canals, nasolabial folds, axillae, chest, and back (Figure 46-7). In infants it is known as *cradle cap.* The cause is unknown, but genetic predisposition, the production of specific phospholipases from the presence of *Malassezia yeasts, and immune responses* are implicated.[47,48] The lesions appear from infancy to old age, with periods of remission and exacerbation. The lesions appear as greasy, scaly, white, or yellowish inflammatory plaques in sebaceous areas with mild pruritus. Mild cases are treated with shampoos containing sulfur, salicylic acid, or tar. Ketoconazole has antifungal and anti-inflammatory effects and has been used with success along with topical calcineurin inhibitors. Corticosteroid applications are useful for suppression of severe symptoms but should not be used for maintenance therapy.[49]

Papulosquamous Disorders

Psoriasis, pityriasis rosea, and lichen planus are inflammatory disorders characterized by papules, scales, plaques, and erythema. Collectively they are described as **papulosquamous disorders.**

Psoriasis

Psoriasis is a chronic, relapsing, proliferative, inflammatory disorder that involves the skin, scalp, and nails and can occur at any age. The disease affects about 1% to 8% of the world population and is more common in countries north of the equator.[50] The onset is generally established by 20 years of age. A family history of psoriasis is common. The genetic mechanisms are complex and the human leukocyte antigen (HLA)-Cw6 allele *(PSORS1)* is a major susceptibility gene that affects skin barrier function and innate immune responses.[51] Psoriasis is a T helper (Th) cell–mediated autoimmune disease. The interleukin (IL)-23/T helper (Th) 17 cell axis plays an important role in the pathogenesis of psoriasis.[52] Inflammatory cytokines involved include tumor necrosis factor-alpha (TNF-α), interferon-gamma (IFN-γ), IL-6, IL-12, IL-15, IL-17, IL-20, IL-21, and IL-22 derived from activated T cells, B cells, dendritic cells, and macrophages.[53]

The dermis and epidermis are thickened with keratinocyte hyperproliferation, altered keratinocyte differentiation, expanded dermal vasculature, infiltration of neutrophils and lymphocytes, and inflammation.[54] The turnover time for shedding the epidermis is decreased from the normal 26 to 30 days to 3 to 4 days. There are increased numbers of germinative cells and an increase in transit time of cells through the dermis. The rapid cellular proliferation does not allow time for cell maturation and keratinization to occur, resulting in a thickened epidermis and plaque formation. The loosely cohesive keratin gives the lesion a silvery, scaly appearance. There is often capillary dilation and increased vascularization to accommodate the increased cell metabolism. The increased vascularity causes erythema.

The types of psoriasis include plaque (psoriasis vulgaris), inverse, guttate, pustular, and erythrodermic. **Plaque psoriasis** is the most common and affects 80% to 90% of individuals with psoriasis. The disease can be mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions. Early onset psoriasis is an inflammatory lesion with epidermal hyperproliferation and the presence of activated T lymphocytes. The typical lesion of plaque psoriasis is a well-demarcated, thick, silvery, scaly, erythematous plaque surrounded by normal skin (Figure 46-8). Initial lesions usually develop insidiously as small erythematous papules that enlarge and coalesce into larger inflammatory lesions that can be painful. The lesions are commonly located on the scalp, elbows, and knees and at sites of trauma. The scales are usually loosely adherent and may cause small bleeding points when removed. **Inverse psoriasis** is rare and involves lesions that develop in skinfolds (i.e., axilla or groin). They are large, smooth, dry, and deep red. The clinical course of psoriasis is characterized by remissions and exacerbations. Psoriasis may be triggered by drugs including antimalarials, lithium, nonsteroidal anti-inflammatories, and beta-blockers.[55]

In **guttate psoriasis,** small papules (1 to 10 mm) appear suddenly on the trunk and extremities (Figure 46-9). The lesions may appear a few weeks after a streptococcal respiratory tract infection and are more common in children. Guttate psoriasis may resolve spontaneously in weeks or months. **Pustular psoriasis** appears as blisters of noninfectious pus (collections of neutrophils) that develop over areas of plaque psoriasis.

FIGURE 46-9 Guttate Psoriasis after Streptococcal Infection. Numerous uniformly small lesions may abruptly occur after streptococcal pharyngitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-10 Pityriasis Rosea Herald Patch. A collarette pattern has formed around the margins. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Erythrodermic (exfoliative) psoriasis is characterized by widespread red, scaling lesions that cover a large body surface area (BSA) and is often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.

Psoriatic arthritis (PsA) and ankylosing spondylitis are associated with the proinflammatory cytokines that cause psoriatic skin lesions. Joints of the hands, feet, knees, and ankles are involved, and 5% to 50% of individuals with psoriasis have seronegative joint involvement. Psoriatic arthritis mutilans involves pronounced bone destruction and there is greater risk of cardiovascular disease with PsA.[56,57] **Psoriatic nail disease** can occur in all psoriasis subtypes with pitting, onycholysis, subungual hyperkeratosis, and nail plate dystrophy. Psoriasis also is a risk factor for a number of comorbidities including inflammatory bowel disease; metabolic syndrome, including hypertension insulin resistance, dyslipidemias, and abdominal obesity; and increased risk for atherosclerosis and cardiovascular disease that is independent of traditional risk factors for these diseases.[58,59]

Treatment is individualized and related to maintaining skin moisture, reducing epidermal cell turnover and itching, and improving immunomodulation. Mild lesions are usually treated with emollients, keratolytic agents, and corticosteroids. Moderate lesions may respond to UVB light, tar preparations, or a combination of both, and to methotrexate, cyclosporine A, and acitretin. Moderate to severe disease is responsive to the photosensitizing agent oral psoralen in combination with UVA light (PUVA), although skin cancer risk (melanoma and squamous cell) with cumulative dose remains a valid concern.[60] Vitamin D_3 (calcitriol) is used to reduce epidermal proliferation. Moderate to severe disease is the indication for biologic treatment including TNF-α blockers (adalimumab, etanercept, infliximab) and interleukin (IL)-12/-23 inhibitors (ustekinumab). Clinical trials are evaluating new agents.[61,62]

Pityriasis Rosea

Pityriasis rosea is a benign self-limiting inflammatory disorder that occurs more often in young adults, with seasonal peaks in the spring and fall. This is a benign disorder except when contracted during pregnancy, when risks are increased for miscarriage and premature delivery.[63] The cause is unknown but is thought to be associated with a virus (e.g., human herpesvirus 6 [HHV-6] and HHV-7) because of the timing and clustering of the outbreaks.[64] Pityriasis rosea begins as a single lesion known as a **herald patch** (Figure 46-10) that is circular, demarcated, and salmon-pink; is approximately 3 to 4 cm in diameter; and is usually located on the trunk. Early lesions are macular and papular; secondary lesions develop within 14 to 21 days and extend over the trunk and upper part of the extremities. Lesions are rarely located on the face. They emerge as small erythematous papules that expand into characteristic oval lesions. There may be few or hundreds of lesions. The pattern of distribution follows the skin lines around the trunk and resembles a drooping pine tree. As scales flake off from the margin of the lesions, a collarette pattern is formed. Itching is the most common symptom. Headache, fatigue, or sore throat may precede the development of the lesions.

The diagnosis of pityriasis rosea is made by the clinical appearance of the lesion. Secondary syphilis, psoriasis, drug eruption, nummular eczema, and seborrheic dermatitis are among the differential diagnosis considerations. The disorder is usually self-limiting and resolves in a few months with symptomatic treatment for pruritus or cosmetic concerns. UV light (with some risk for hyperpigmentation), antihistamines, or topical corticosteroids may be used to control itching. Erythromycin and acyclovir also may be used for treatment.[65]

Lichen Planus

Lichen planus (LP) is a benign, autoimmune inflammatory disorder of the skin and mucous membranes with multiple clinical variations. The cause is unknown, but T cells, adhesion molecules, inflammatory cytokines, perforin, and antigen-presenting cells are involved.[66] The infiltrate of T cells mediates immunoreactivity against basal layer keratinocytes, which have altered surface antigens and adhesion molecules.[67] LP is also linked to hepatitis C virus. Some individuals develop lichenoid lesions after exposure to drugs or film-processing chemicals. The age of onset is usually between 30 and 70 years. The disorder begins with flat purple, polygonal, pruritic, nonscaling papules 2 to 4 mm in size, usually located on the wrists, ankles, lower legs, and genitalia (Figure 46-11). New lesions are pale pink and evolve into a dark violet. Persistent lesions may be thickened and red, forming hypertrophic LP. Oral lesions

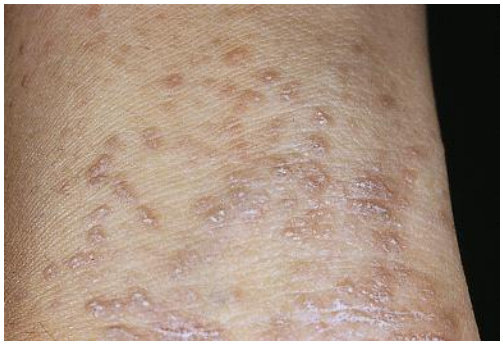

FIGURE 46-11 Hypertrophic Lichen Planus on Arms. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

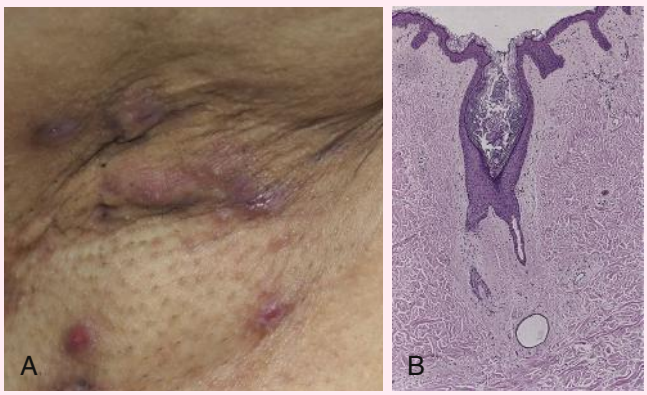
(oral lichen planus) appear as lacy white rings that must be differentiated from leukoplakia or oral candidiasis and they may be precancerous lesions.[68] Fine white lines, known as Wickham striae, can be seen throughout the oral lesions on magnification. These lesions also can develop on the penis and vulvovaginal area. More commonly, oral lesions do not ulcerate, but localized or extensive painful ulcerations do, and frequently, occur. Chronic ulcerated lesions become malignant in 1% of individuals with the disease. Thinning and splitting of nails are common, and part or all of the nail may be shed.

Pruritus is the most distressing symptom. The lesions are self-limiting and may last for months or years, with an average duration of 6 to 18 months. Postinflammatory hyperpigmentation is a common consequence of the lesion. Approximately 20% of individuals have a recurrence. Diagnosis is commonly made by the clinical appearance of the lesion; however, histopathologic diagnosis is recommended. For cutaneous LP, treatment is individualized and includes topical, intralesional, or systemic corticosteroids (second line for resistant LP), and systemic acitretin with/without adjuvant light therapy. Antihistamines are given for itching, and topical or systemic corticosteroids may be used to control inflammation. Short-term systemic glucocorticoids are indicated if oral lesions are severe or for LP involving three or more nails. Mucous membrane lesions are treated with potent topical steroids, topical retinoids, and systemic glucocorticoids.[69-71]

Acne Vulgaris

Acne vulgaris is an inflammatory disorder of the pilosebaceous follicle (the sebaceous gland contiguous with a hair follicle). It occurs most commonly during adolescence. Details of this disorder are presented in Chapter 47. Hidradenitis suppurativa (inverse acne) is summarized in What's New? Hidradenitis Suppurativa (Inverse Acne).



Acne Rosacea

Acne rosacea is a chronic, readily exacerbated, inflammatory skin disease with varied presentations and extent of involvement that develops primarily in middle-age adults. There are four types of lesions: erythematotelangiectatic, papulopustular, phymatous, and ocular.[72] They occur in the middle third of the face, including the forehead, nose, cheeks, and chin (Figure 46-12). The cause is unknown, but immune-mediated inflammation may be a factor. The lesions are associated with chronic,

WHAT'S NEW?

Hidradenitis Suppurativa (Inverse Acne)

Hidradenitis suppurativa (inverse acne) is a chronic, inflammatory, recurring, scarring disease of the pilosebaceous follicular ducts involving areas of skin where there are folds, hair follicles, and apocrine (sweat) glands (i.e., axillary, inguinal, inframammary, genital, buttocks, and perineal areas of the body) (see figure). The incidence is unknown but estimated at 1% to 4% of the population and is more common in females. The pathogenesis of the disease is complex and includes a combination of genetic, hormonal, immune, and environmental factors. Aggravating factors include tight clothing, heat and perspiration, obesity, stress, and smoking. Follicular hyperkeratosis and occlusion obstructs the pilosebaceous unit, causing perifolliculitis, abscess formation, sinus tracts, and scarring. Bacterial infection is a secondary event. The lesions present as deep, firm, painful subcutaneous nodules that track and rupture horizontally under the skin. They are differentiated from "boils" (carbuncles) because boils extend vertically and discharge onto the skin. Diagnosis can be difficult, delaying effective treatment. Treatment can include administering systemic medications, performing incision and drainage of nodules, obtaining a culture of the exudate, and giving antibiotics, with concern about the presence of methicillin-resistant *Staphylococcus aureus* (MRSA), topical or intralesional corticosteroids, and retinoids. Lesions often require surgical excision and skin grafting. Complete, spontaneous resolution is rare. Deterrence includes avoiding heat and perspiration, losing weight if obese, wearing loose clothing, refraining from shaving affected areas, stopping smoking, and using zinc gluconate supplements to reduce inflammation. The disease can recur for years with negative effects on quality of life. Clinical trials are needed to identify the best treatment options.

inappropriate vasodilation resulting in flushing and sensitivity to the sun. Sebaceous hypertrophy, fibrosis, and telangiectasia may be severe enough to produce an irreversible bulbous appearance of the nose, known as *rhinophyma.* The vascular abnormalities induce local production of transforming growth factor-β1 (TGF-β1) capable of creating fibrosis and, therefore, cutaneous thickening.[73] *Demodex folliculorum* (mites) infection may be a contributing factor.[74] Disorders of the eye often accompany rosacea, particularly conjunctivitis and, more rarely, keratitis, which can result in visual impairment.[75] Facial application of fluorinated topical steroids may precipitate rosacea-like lesions that are difficult to treat.

Hot drinks or alcohol should be taken cautiously because the heat and vasodilation accentuate erythema. Daily use of photoprotection, including sunscreens, is recommended; both topical (metronidazole, azelaic acid) and oral drugs (tetracyclines) may be effective.[76] Surgical excision of excessive tissue may be required for rhinophyma.

Lupus Erythematosus

Lupus erythematosus is an inflammatory, autoimmune, systemic disease with cutaneous manifestations. Discoid (or cutaneous) lupus erythematosus (DLE) is limited to the skin and can progress to systemic lupus erythematosus (SLE). DLE may be described as a subset of SLE, with cutaneous manifestations as the only symptom[77] (Figure 46-13). (SLE, a diffuse, multisystem disease that also has cutaneous manifestations, is discussed in Chapter 9.)

Discoid (Cutaneous) Lupus Erythematosus. **Discoid (cutaneous) lupus erythematosus (DLE)** usually occurs in genetically susceptible adults, particularly in women in their late thirties or early forties. There are three forms of the disease: acute, subacute, and chronic. The lesions may be single or multiple and of various sizes. Often the lesions are located on light-exposed areas of the skin, and photosensitivity is common. The face is the most common site of lesion involvement. The characteristic manifestations of the different categories of DLE are summarized in Table 46-6.

The cause is unknown but thought to be related to genetic and environmental factors and an altered immune response to an unknown antigen or response to UV wavelengths with the development of self-reactive T and B cells, decreased number of regulatory T cells, and increased proinflammatory cytokines. Autoantibodies and immune complexes cause tissue damage.[78]

FIGURE 46-13 Subacute Cutaneous Lupus (Discoid Lupus Erythematosus). (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Diagnosis of DLE is made from the presenting symptoms, biopsy of skin lesions with direct immunofluorescence, as well as histologic results. Skin biopsy with immunofluorescent observation reveals lumpy deposits of immunoglobulins, especially IgM and C3.[79] DLE can progress to systemic lupus erythematosus and individuals with SLE should be regularly screened for this progression.[80]

Individuals with DLE must use sunscreen and sun protection because direct sun exposure initiates or exacerbates lesions. Treatment options include topical steroids, calcineurin inhibitors, antimalarial drugs (e.g., hydroxychloroquine sulfate), and immunosuppressors. These medications must be used with caution to prevent serious side effects.[81]

Vesiculobullous Disorders

Vesiculobullous skin diseases share a common characteristic of vesicle, or blister, formation. Two such diseases are pemphigus and erythema multiforme.

Pemphigus

Pemphigus (meaning to blister or bubble) is a rare autoimmune blistering disease of the skin and oral mucous membranes caused by circulating autoantibodies directed against the cell surface adhesion molecule desmoglein at the desmosomal cell junction in the suprabasal layer of the epidermis. Pemphigus

TABLE 46-6 CATEGORIES AND MANIFESTATIONS OF DISCOID LUPUS ERYTHEMATOSUS (DLE)

CATEGORY OF DLE	CLINICAL MANIFESTATIONS
Acute	
Localized	Butterfly pattern of erythema over bridge of nose and malar areas of face (malar rash); may have fine surface scales and underlying edema; scalp areas may develop alopecia; lasts for hours to days
Generalized	Diffuse or papular erythema of face, upper trunk, or extremities; develops quickly and lasts hours to days
Subacute	Erythematous macules and papules that evolve into *papulosquamous* or *annular* plaques developing on sun-exposed areas of the upper body (V area of neck, upper chest, back, shoulders, extensor surface of arms and hands); can be associated with reaction to drugs; may be accompanied by mild systemic disease
Chronic	Classic discoid lupus erythematosus is the most common form; lesions are red to purple macules or papules with a superficial brownish scale; scale can penetrate hair follicle leaving a carpet-tack appearance when removed; may have residual scarring, dermal atrophy hypopigmentation, alopecia, and telangiectasia; Raynaud phenomenon occurs in some individuals

Data from Kuhn A, Biji M: *Lupus* 17(5):389–393, 2008; Rothfield N, Sontheimer RD, Bernstein M: *Clin Dermatol* 24(5):348–362, 2006; Uva L et al: *Autoimmune Dis* 2012:834291, 2012.

can occur in all age groups but is more prevalent between 40 and 50 years of age. There is a genetic predisposition as well as environmental triggers, most of which are unknown.[82] Pemphigus presents in varying forms:

- **Pemphigus vulgaris** is the most common form with acantholysis at the suprabasal level. Immunoglobulin G (IgG) autoantibodies and C3 complement bind to the desmoglein adhesion molecules, resulting in the destruction of cell-to-cell adhesion (acantholysis) in the epidermis with fluid accumulation and the resulting symptom of blister formation.[83] Oral lesions precede the onset of skin blistering, which is more prominent on the face, scalp, and axilla. The blisters rupture easily because of the thin, fragile overlying portion of epidermis, resulting in painful erosions. *Pemphigus vegetans* is a rare variant of pemphigus vulgaris with large blisters that progress to hypertrophic granulomas with tissue erosion and pustules (vegetating plaques). They usually occur in tissue folds.
- **Pemphigus foliaceus** is a milder form of the disease and involves acantholysis at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest. Oral mucous membranes are rarely involved. *Pemphigus erythematosus* is a subset of pemphigus foliaceus often associated with systemic lupus erythematosus with positive antinuclear antibodies. The lesions are generally less widely distributed.
- **Paraneoplastic pemphigus** is the most severe form of pemphigus and is associated with lymphoproliferative neoplasms. Internal organs, including lungs, thyroid, kidney, smooth muscle, and the gastrointestinal tract, also are involved, leading to the term *paraneoplastic autoimmune multiorgan syndrome.* In contrast to pemphigus vulgaris, the lesions develop from inflammatory papules or macules rather than normal skin.[84]
- **IgA pemphigus** is the most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis. Acantholysis is not as severe as that in pemphigus vulgaris but there is still blister formation.[85]

The diagnosis of pemphigus is made from the clinical manifestations and histologic examination of the skin. Immunofluorescence demonstrates the presence of antibodies at the site of blister formation. The clinical course of the disease may range from rapidly fatal to relatively benign. The primary treatment for pemphigus is systemic corticosteroids in combination with adjuvant immunosuppressants and, in difficult cases, adjuvant protein A immunoadsorption intravenous immunoglobulins, plasmapheresis, and anti-CD20 monoclonal antibody therapy. Newer methods of treatment and a clearer understanding of the pathogenesis have improved the prognosis and decreased mortality.[86]

Bullous Pemphigoid

Bullous pemphigoid (BP) is a more benign autoimmune disease than pemphigus vulgaris, with blistering of the subepidermal skin layer. Autoantibodies (IgG and IgE) to hemidesmosomal proteins designated BP 180 and BP 230 have been found. There are numerous triggers, including drugs and skin trauma. The autoantibodies activate complement with inflammatory infiltration of neutrophils, eosinophils, and lymphocytes. Loss of dermal-epidermal adhesion is caused by inflammatory cytokines.[87,88] The lesions of pemphigoid begin with localized erythema or as pruritic plaques that extend and become edematous. The plaques turn reddish purple by 2 to 3 weeks, with vesicles and bullae emerging on the surface (Figure 46-14). Oral lesions can occur. The bullae do not extend with pressure. The blisters rupture within 1 week and heal rapidly. BP occurs more commonly after 60 years of age.

Diagnosis is by skin biopsy and immunofluorescent examination. The presence of subepidermal blistering and eosinophils distinguishes pemphigoid from pemphigus. Treatment usually includes hydroxyzine (Atarax) for itching and topical or systemic corticosteroids. Adjuvant immunosuppressive drugs may be prescribed. Relapse may occur with discontinuation of treatment.[89,90]

Erythema Multiforme

Erythema multiforme is not a single disease but rather a syndrome characterized by inflammation of skin and mucous

FIGURE 46-14 Bullous Pemphigoid. Generalized eruption with blisters arising from an edematous, erythematous annular base. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

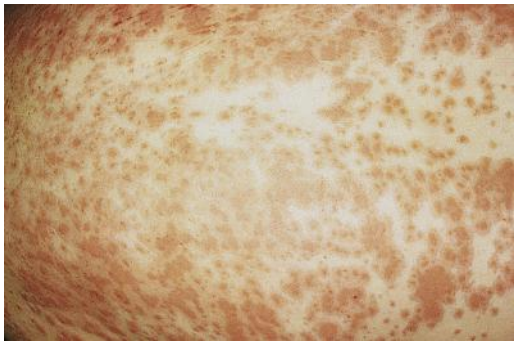

FIGURE 46-15 Erythema Multiforme Caused by Doxepin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

membranes. It often is associated with a T-cell–mediated immunologic reaction to microorganisms (e.g., herpes simplex virus, *Mycoplasma pneumoniae*) or a toxic reaction to drugs in which TNF-α causes tissue damage.[91] Overall, it is relatively rare and can occur at any age but is more common between 20 and 40 years of age. Immune complex formation and deposition of complement (C3), IgM, and fibrinogen around the superficial dermal blood vessels, basement membrane, and keratinocytes are found in most individuals with erythema multiforme. Edema develops in the superficial dermis, leading to the formation of vesicles and bullae. The lesions vary in clinical presentation and may involve the skin or mucous membranes, or both. The characteristic "bull's-eye" or "target" lesions occur on the skin surface with a central dusky region surrounded by concentric rings or alternating edema and inflammation.[92,93] The lesions usually occur suddenly in groups over 2 to 3 weeks. Urticarial plaques, 1 to 2 cm in diameter, can develop without the target lesion. A vesiculobullous form is characterized by mucous membrane lesions and erythematous plaques over elbows and knees. Single or multiple vesicles or bullae may arise on a part of the plaque, accompanied by pruritus and burning. In the minor form, there may be tens to hundreds of lesions.[94] The lesions heal within 3 to 4 weeks (Figure 46-15).

Prodromal symptoms of erythema multiform include fever, headache, malaise, sore throat, and cough in approximately one third of cases. The bullous lesions form erosions and crusts when ruptured. The mouth, air passages, esophagus, urethra, and conjunctiva may be involved when mucous membranes are affected. Blindness can result from corneal ulcerations. Difficulty with eating, breathing, and urinating may develop with severe manifestations. Severe forms of the disease can be fatal.

Diagnosis is made by medication history, by recognition of the target lesion, or by skin biopsy to establish the diagnosis. Mild, acute forms of the disease last 10 to 14 days, are usually self-limiting, and require no treatment. Any ongoing drug therapy should be withdrawn or reevaluated and underlying infections treated. Treatment is individualized according to severity.[93] Antiviral prophylaxis may be required. Fluid and electrolyte balance should be monitored in severe forms of the disease, and mucous membranes must be carefully managed with a bland diet, warm saline eyewashes, topical anesthetics, or corticosteroids to maintain comfort and prevent infection. Use of systemic steroids is controversial. Cutaneous blisters can be treated with wet compresses of nanocrystalline silver. Ophthalmic, kidney, and lung involvement requires special care. Resolution occurs in 8 to 10 days, usually without scarring. Mucosal lesions may take 6 weeks to heal.[93]

Infections

Cutaneous infections are common forms of skin disease. They generally remain localized; however, serious complications can develop with systemic involvement. The types of skin infection include bacterial, viral, and fungal. Most infections occur superficially; however, systemic signs and symptoms occasionally develop and rarely become life threatening. Aerobes, yeast, and anaerobes comprise the normal flora of the skin and often provide protection against pathogens that cause skin infections, including *Staphylococcus* and *Streptococcus.*

Bacterial Infections

Most bacterial infections of the skin are caused by local invasion of pathogens. Coagulase-positive *Staphylococcus aureus* and, less often, beta-hemolytic *Streptococci* are the common causative microorganisms. Community-acquired methicillin-resistant *Staphylococcus aureus* (CA-MRSA) is also a cause of serious skin infection (Box 46-3).

Folliculitis. **Folliculitis** is an infection of the hair follicle and can be caused by bacteria, viruses, or fungi. *S. aureus* is a common causative microorganism.[95] The infection develops from proliferation of the microorganism around the opening of the follicle and then spreads into the follicle. Inflammation is caused by the release of chemotactic factors and enzymes from the bacteria. The lesions appear as pustules with a surrounding area of erythema. They are most prominent on the scalp and extremities and rarely cause systemic symptoms. Prolonged skin moisture, occlusive clothing, topical agents, skin trauma (e.g., shaving facial hair), and poor hygiene are associated contributing factors to the development of folliculitis. Cleaning with soap and water and topical application of antibiotics are effective forms of treatment.

Furuncles and Carbuncles. A **furuncle,** or "boil," is an inflammation of the hair follicles that may develop from a preceding folliculitis and spread through the follicular wall into the surrounding dermis. The invading microorganism is

BOX 46-3 COMMUNITY-ACQUIRED METHICILLIN-RESISTANT *Staphylococcus aureus* (CA-MRSA)

CA-MRSA is a serious skin and soft tissue infection that includes abscesses, cellulitis, and necrotizing fasciitis, and can serve as a source for bloodstream infections. Infections are documented among healthy individuals who have no known risk factors, that is, no recent hospitalization, surgical procedures, or prolonged antibiotic treatment. Outbreaks have been documented among athletic teams, among prisoners, and in daycare centers. CA-MRSA strains are epidemiologically and clonally different from hospital- or nursing home–acquired MRSA. The most common tests involve genotyping for the staphylococcal chromosomal cassette mec (SCCmec) type IV and Panton-Valentine leukocidin genes. The USA300-0114 strain has been epidemic in the United States. It also has caused life-threatening pneumonia, osteomyelitis, and septic arthritis and is spreading internationally.

CA-MRSAs are more sensitive to antibiotic treatment and there is a wider choice of antibiotic treatment options for CA-MRSA compared with hospital-acquired MRSA. CA-MRSA is usually susceptible to a variety of oral non–beta-lactam antibiotics, including trimethoprim-sulfamethoxazole, clindamycin, tetracyclines, and linezolid. Parenteral therapy with vancomycin or daptomycin also can be considered. Ceftaroline has been effective for both skin and systemic infections. Mupirocin may be used to clear MRSA from nasal secretions if cultures show contamination in the nose. New drugs are under investigation. Preventive measures include practicing good hand hygiene, applying antiseptics and covering cuts and abrasions, using antibacterial soaps for showers after contact sports, avoiding sharing towels and razors, and frequently washing towels.

usually *S. aureus,* including community-associated methicillin-resistant *S. aureus* (CA-MSRA). The infecting strain may spread to the skin from the anterior nares. Any skin area with hair can be infected, and one or several lesions may be present. The precipitating events are similar to those for folliculitis. The initial lesion is a deep, firm, red, painful nodule 1 to 5 cm in diameter (Figure 46-16). Within a few days the initial erythematous nodule changes to a large fluctuant and tender cystic nodule that may be accompanied by cellulitis. No systemic symptoms are present, and the lesion may drain large amounts of pus and necrotic tissue.[96]

A **carbuncle** is a collection of infected hair follicles occurring most often on the back of the neck, the upper back, and the lateral thighs. The lesion begins in the subcutaneous tissue and lower dermis as a firm mass that evolves into an erythematous, painful, swollen mass that drains through many openings. Abscesses may develop. Chills, fever, and malaise are systemic symptoms that can occur during the early stages of lesion development.

Furuncles and carbuncles are treated with warm compresses to provide comfort and promote localization and spontaneous drainage. Abscess formation requires incision and drainage and recurrent infections, extensive lesions, or those associated with cellulitis or systemic symptoms are treated with systemic antibiotics.

Cellulitis. **Cellulitis** is an infection of the dermis and subcutaneous tissue usually caused by *Staphylococcus,* CA-MRSA, or group B streptococci. Cellulitis can occur as an extension of a skin wound, of an ulcer, or from furuncles or carbuncles. It can be associated with chronic venous insufficiency and stasis dermatitis. Risk factors include diabetes mellitus, edema, peripheral vascular disease, tinea pedis, insect bites, and immune suppression. The infected area is erythematous, warm, swollen, and painful and can extend to lymph nodes and the blood. Initial systemic treatment with antibiotics should cover both *Staphylococci* and *Streptococci,* and Burrow soaks can be used to relieve pain. Corticosteroids are used for adjuvant therapy.[97]

Cellulitis must be differentiated from **necrotizing fasciitis.** Necrotizing fasciitis is a rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is treated with antibiotics and often requires surgical débridement.[98]

Erysipelas. **Erysipelas** is an acute superficial infection of the upper dermis (a superficial form of cellulitis) most often caused by *Streptococcus pyogenes,* beta-hemolytic streptococci, and *Staphylococcus aureus*. The face, ears, and lower legs are common sites of involvement, and the site of initial infection may not be identified. Chills, fever, and malaise precede the onset of lesions by 4 hours to 20 days. The initial lesions appear as firm, red spots that enlarge and coalesce to form a clearly circumscribed, advancing edge, bright red, hot lesion with a raised border. Vesicles may appear over the lesion and at the border, producing a bullous form of the disease. Itching, burning, and tenderness accompany the development of the lesion. Cold compresses provide symptomatic relief, and systemic antibiotics are required to arrest the infection.[99]

Impetigo. **Impetigo,** most common in children, is a superficial lesion of the skin caused by coagulase-positive *Staphylococcus aureus* or alpha-hemolytic streptococci[100] (see Chapter 47).

FIGURE 46-17 Herpes Simplex. Typical presentation with tense vesicles involving the nasal mucosa and extending onto the skin. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 4, Philadelphia, 2004, Mosby.)

FIGURE 46-18 Herpes Zoster. Diffuse involvement of a dermatome. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Viral Infections

Herpes Simplex Virus. Skin infections with **herpes simplex virus (HSV)** are commonly caused by two types: HSV-1 and HSV-2. Either type can occur in different parts of the body, including oral and genital locations. Their differences are distinguished by laboratory tests. HSV-1 is generally associated with oral infections (cold sore or fever blister) or infection of the cornea (herpes keratitis) but it also can cause genital herpes.[101] HSV-1 is usually transmitted by contact with infected saliva. With primary infection, the virus infects epithelial cells and moves by retrograde axonal transport to the dorsal root ganglion, where the virus develops lifelong latency. The incubation period ranges from 2 to 14 days. During the secondary phase, the lesions occur at the same site from reactivation of the virus. The virus travels down the peripheral nerve to the site of the original infection, where it is shed. Exposure to ultraviolet light, skin irritation, fever, fatigue, or stress may cause reactivation.

The lesions for HSV-1 appear as a rash or clusters of inflamed and painful vesicles (e.g., within the mouth, over the tongue, on the lips, within and/or around the nose) (Figure 46-17). Increased sensitivity, paresthesias, and mild burning often occur before onset of the lesions. The vesicles rupture, forming a crust. Lesions may last from 2 to 6 weeks. Treatment is symptomatic and includes topical antiviral agents; lesions usually resolve within 2 weeks. Oral antivirals may be indicated at the time of acute infection or through daily suppressive dosing to prevent acute infections.[102]

Genital infections are more commonly caused by HSV-2. The virus is spread by skin-to-skin mucous membrane contact during viral shedding. Risk of infection is high after sexual contact with infected individuals and for those who are immunosuppressed and there is increased risk for human immunodeficiency virus (HIV) infection. Vertical transmission from mother to neonate is associated with significant neonatal neurologic morbidity and mortality.[103] The primary infection is asymptomatic. With recurrent exposure, the lesions begin as small vesicles that progress to ulceration within 3 to 4 days with pain, itching, and weeping. Treatment is symptomatic and includes topical or oral antiviral agents. Efforts are in progress to develop prophylactic vaccines.[104]

Herpes Zoster and Varicella. **Herpes zoster** (shingles) and **herpes varicella** (chickenpox, see Chapter 47) are caused by the same herpes virus—varicella-zoster virus (VZV). VZV is the primary infection followed years later by herpes zoster (shingles) from reactivation of the virus, particularly among those who are immunosuppressed.[105] It can cause severe disease in nonimmune pregnant women. Following the primary infection the virus remains latent in trigeminal and dorsal root ganglia.

Herpes zoster has initial symptoms of pain and paresthesia localized to the affected dermatome (the cutaneous area innervated by a single spinal nerve; see Chapter 15), followed by vesicular eruptions along a facial, cervical, or thoracic lumbar dermatome (Figure 46-18). Some individuals have vesicles scattered outside the area of the dermatome but lesions do not usually cross the midline. Local symptoms are alleviated with compresses, calamine lotion, or baking soda. Persistent pain may last for weeks or months and is a debilitating complication, particularly in older adults, and requires treatment. Approximately 15% to 20% of individuals experience postherpetic neuralgias.[106] There is no cure for herpes zoster. Antiviral drugs are useful if used within the first 72 hours.[107] Treatment includes a topical lidocaine patch, anticonvulsant medication, controlled-release narcotics, tricyclic antidepressants, and topical capsaicin.[108] Because older adults are at increased risk due to declining immunocompetence, the live-attenuated varicella vaccine is recommended for those older than age 60 as it is well tolerated and effective and may boost humoral and cellular immunity.[109,110]

Warts. **Warts** (verrucae) are benign lesions of the skin caused by the many different types of **human papillomavirus (HPV)** that infect the stratified epithelium of skin and mucous

FIGURE 46-19 Verruca Vulgaris. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

membranes. Specific viruses are associated with specific kinds and locations of lesions.[111] The lesions are round and elevated with a rough, grayish surface; can occur anywhere on the skin; and are transmitted by touch. *Common warts* (verrucae vulgaris) occur most often in children and are usually on the fingers, although they may be located on any skin surface or mucous membrane. Warts vary in shape, size (flat, round, or fusiform), and location (Figure 46-19). Plantar warts are usually located at pressure points on the bottom of the feet.

Diagnosis of warts is by visualization. Treatment considers age of the individual and size and location of the lesion. Warts can be removed by freezing with liquid nitrogen, electrocauterization, vaporization with lasers, application of keratolytics, or application of irritants and corrosives such as salicylic acid, formaldehyde, interferons, or podophyllum.[112] Recalcitrant warts may benefit from application of topicals such as imiquimod 5% cream (immunomodulatory) or 5-fluorouracil, by intralesional injections of bleomycin or *Candida* (immunoreactive antigen), or by more aggressive surgical procedures.[113] Many warts resolve spontaneously but often recur.

Condylomata acuminata (venereal warts) are highly contagious and sexually transmitted. The cauliflower-like lesions occur in moist areas along the glans of the penis, vulva, and anus (see Chapter 26). Oncogenic HPV (e.g., types 16 and 18) is a primary cause of cervical cancer (see Chapter 24).

Fungal Infections

The fungi causing superficial skin infections are called *dermatophytes,* and they thrive on keratin (stratum corneum, hair, nails). Fungal disorders are known as *mycoses;* when caused by dermatophytes, the mycoses are termed *tinea* (dermatophytosis or ringworm).

Tinea Infections. **Tinea infections** are fungal infections of the skin and are classified according to their location on the body.[114] The most common sites are summarized in Table 46-7. These infections are common in children (see Chapter 47). **Tinea unguium (onychomycosis)** is a fungal infection of the nails and is discussed on p. 1647. **Tinea pedis** is a chronic, superficial fungal infection of the skin of the foot common in adults (Figure 46-20). In prepubertal children, most scaling disorders of the toes and feet are eczema. **Tinea corporis (ringworm)** and **tinea capitis** (a fungal infection of the scalp) are much more common in children than adults. (See Chapter 47 for a discussion of fungal infections in children.)

Tinea is diagnosed by culture, microscopic examination of skin scrapings prepared with potassium hydroxide wet mount, or observation of the skin with a UV light (Wood lamp).

TABLE 46-7 COMMON SITES OF TINEA INFECTIONS

SITE	CLINICAL MANIFESTATIONS
Tinea capitis (scalp)	Scaly, pruritic scalp with bald areas; hair breaks easily
Tinea corporis (skin areas, excluding scalp, face, hands, feet, groin)	Circular, clearly circumscribed, mildly erythematous scaly patches with a slightly elevated ringlike border; some forms are dry and macular, and other forms are moist and vesicular
Tinea cruris (groin, also known as "jock itch")	Small erythematous and scaling vesicular patches with a well-defined border that spreads over the inner and upper surfaces of the thighs; occurs with heat and high humidity
Tinea pedis (foot, also known as "athlete's foot")	Occurs between the toes and may spread to the soles of the feet, nails, and skin of toes; slight scaling, macerated painful skin, occasionally with fissures and vesiculation
Tinea manus (hand)	Dry, scaly, erythematous lesions, or moist vesicular lesions that begin with clusters of intensely itching, clear vesicles; often associated with fungal infection of the feet
Tinea unguium or onychomycosis (nails)	A superficial or deep inflammation of the nail that develops yellow-brown accumulations of brittle keratin over all or portions of the nail

FIGURE 46-20 Tinea Pedis. Inflammation has extended from the web area onto the dorsum of the foot. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

TABLE 46-8 SITES OF CANDIDIASIS

SITE	RISK FACTORS	CLINICAL MANIFESTATIONS	TREATMENT
Vagina (vulvovaginitis)	Heat, moisture, occlusive clothing Pregnancy Systemic antibiotic therapy Diabetes mellitus Sexual intercourse with infected male	Vaginal itching; white, watery, or creamy discharge Red and swollen vaginal and labial membranes with erosions Lesions may spread to anus and groin	Miconazole cream Clotrimazole tablets or cream Nystatin tablets Ketoconazole cream Loose cotton clothing
Penis (balanitis)	Uncircumcised Sexual intercourse with infected female	Pinpoint, red, tender papules and pustules on glans and shaft of penis	Any of creams listed above Topical steroids for severe inflammation
Mouth	Diabetes mellitus Immunosuppressive therapy Inhaled steroids	Red, swollen, painful tongue and oral mucous membranes Localized erosions and plaques appear with chronic infection	Nystatin oral suspension Clotrimazole troches Ketoconazole Fluconazole
Skinfolds	Heat and moisture Diabetes mellitus Immunosuppressive therapy	Pruritic red rash progressing to vesicles and papules that enlarge and rupture	Topical antifungals (e.g., clotrimazole, econazole, ciclopirox, miconazole, ketoconazole, nystatin)

Cultures establish the particular type of fungus and are necessary for hair and nail infections. Fungi have characteristic spores and filaments known as **hyphae** that are more prominent when prepared in potassium hydroxide. The spores fluoresce blue-green when exposed to UV light. Treatment is related to the type of fungi and includes both topical and systemic antifungal medications.

Candidiasis. **Candidiasis** is caused by the yeastlike fungus *Candida albicans* and normally can be found on mucous membranes, on the skin, in the gastrointestinal tract, and in the vagina. *C. albicans* can, under certain circumstances, change from a commensal microorganism to a pathogen, particularly in the critically ill and those who are immunosuppressed.[115] Factors that predispose to infection include: (1) a local environment of moisture, warmth, maceration, or occlusion; (2) the systemic administration of antibiotics; (3) pregnancy; (4) diabetes mellitus; (5) Cushing disease; (6) debilitated states; (7) age younger than 6 months (more likely to get an infection because of decreased immune reactivity); (8) immunosuppression; and (9) certain neoplastic diseases of the blood and monocyte-macrophage system. The resident bacteria on the skin, mainly cocci, inhibit proliferation of *C. albicans.* Cell-mediated immunity plays a major role in the defense against monilial infections. *C. albicans* can activate the complement system by the alternative pathway and can include small abscesses. Candidiasis affects only the outer layers of mucous membranes and skin and occurs in the mouth, vagina, uncircumcised penis, nail folds, interdigital areas, and large skinfolds (inframammary area, intertriginous area, perianal region, and abdominal creases). Table 46-8 lists selected sites of candidiasis. Innate and adaptive immune responses are required for elimination of *C. albicans*.[116]

The initial lesion is a thin-walled pustule that extends under the stratum corneum with an inflammatory base that may burn or itch. The accumulation of inflammatory cells and scale produces a whitish yellow curdlike substance over the infected area. The lesion ceases to spread when it reaches dry skin.[117] Topical antifungal medication is most commonly used for treatment.

Vascular Disorders

Vascular abnormalities are commonly associated with skin diseases, or they may be present as congenital vascular malformations (see Chapter 47) or as vascular responses to local or systemic vasoactive substances. Blood vessels may increase in number, dilate, constrict, or become obliterated by disease processes.

Cutaneous Vasculitis

Cutaneous vasculitis (angiitis) is an inflammation of the blood vessels of the skin. The vasculitis is often idiopathic or can be triggered by infection, decreased blood flow (i.e., venous stasis), drugs, or autoimmune disorders. The initiating site of inflammation may be the blood, the vessel wall, or the adjacent tissue. Small vessels are usually affected. Immune complexes, which initiate an uncontrolled inflammatory response, are often the cause of damage, and the lesions are often polymorphic.

Cutaneous vasculitis develops from the deposit of immune complexes in small blood vessels as a toxic response to drugs (phenothiazines, barbiturates, sulfonamides) or allergens, as a response to streptococcal or viral infection, or as a component of systemic vasculitic syndromes. The precise mechanism is not known, but the deposit of immune complex activates complement, which is chemotactic for polymorphonuclear leukocytes and other mediators of inflammation that disrupt adhesion molecules and the vessel wall. The cutaneous form usually resolves in a few weeks and is treated with steroids.

A systemic form (cutaneous systemic vasculitis) can involve other organs, including the kidneys, lungs, and gastrointestinal tract (e.g., Wegener granulomatosis). The extremities are the chief sites affected, primarily the lower legs and feet. The lesions appear as palpable purpuras (from the leakage of blood from damaged vessels) and progress to hemorrhagic bullae with necrosis and ulceration from occlusion of the vessel (Figure 46-21). Lesions appear in clusters and remain from 1 to 4 weeks. Recurrences are common.

Serum analysis and biopsy provide the most accurate differential diagnosis. Identifying the primary disease or removing

FIGURE 46-21 Vasculitis of the Leg. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-22 Urticaria. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

the antigen (chemical, drug, or source of infection) is the first step of treatment. Corticosteroids and immunosuppressants are used when symptoms are severe.[118,119]

Urticaria

Urticaria (hives) is a pruritic circumscribed area of raised erythema with central pallor occurring in the superficial dermis; they are often generalized in distribution. The erythema blanches with pressure. **Urticarial lesions** are most commonly associated with type I hypersensitivity reactions to drugs (e.g., penicillin, aspirin), certain foods (e.g., strawberries, shellfish), systemic diseases (e.g., intestinal parasites, lupus erythematosus), physical agents (e.g., heat, cold), or complement-mediated reactions (see Chapter 9). They may occur with angioedema (edema of the dermis and subcutaneous tissue). The lesions are usually mediated by IgE-stimulated release of histamine, bradykinin, or kallikrein from mast cells or basophils, or both, which causes the endothelial cells of skin blood vessels to contract, increasing permeability. IgG antibody directed against the IgE receptor and other inflammatory mediators, such as serotonin, leukotrienes, prostaglandins, and kinins, also may be mediators of urticaria. Fluid leakage from vessels appears as wheals, welts, or hives; there may be a few leaks or many leaks distributed over the entire body (Figure 46-22). Most lesions resolve spontaneously within 24 hours, but new lesions may appear. All possible causes should be removed. Nonsedating, second-generation antihistamines (H1 antagonists) usually reduce hives and itching but may be combined with histamine H2 blockers, first-generation antihistamines, or leukotriene receptor agonists to improve outcomes.[120] Epinephrine or corticosteroids and α-adrenergic agonists may be required for treatment of severe attacks (i.e., angioedema). Chronic urticaria (recurrent wheals for more than 6 weeks) is either an autoimmune or an idiopathic disease.[121]

FIGURE 46-23 Scleroderma. Note inflammation and shiny skin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Localized Scleroderma

Localized scleroderma (morphea) means sclerosis of the skin. The disease is rare and the cause is unknown. It is more prominent in white females, usually with childhood onset. Genetic predisposition, autoimmunity, and an immune reaction to a toxic substance are possible initiating mechanisms of the disease. T helper cells (Th1 and Th17) and their cytokines are associated with fibroblast proliferation and fibrosis. Several autoantibodies also have been identified, including antinuclear antibody (ANA), antihistone antibody (AHA), and single-stranded DNA antibody (ss-DNA Ab).[122] The cutaneous lesions are most often on the face and hands, neck, and upper chest, but the entire skin can be involved.

There are massive deposits of collagen with fibrosis, accompanied by inflammatory reactions, vascular changes in the capillary network with a decrease in the number of capillary loops, dilation of the remaining capillaries, enhanced expression of adhesion molecules, endothelial injury and dysfunction, perivascular infiltrates, and ischemia. Fibrosis occurs in the papillary and reticular dermis and in the subcutaneous tissue and deep fascia. The skin is hard, hypopigmented, taut, shiny, and tightly attached to the underlying tissue. The tightness of the facial skin projects an immobile masklike appearance, and the oral aperture is limited. The nose may assume a beaklike appearance. The hands are shiny and sometimes red and edematous (Figure 46-23). The fingers become tapered and flexed, often with contractures, depressed scars, and loss of fingertips from atrophy. Raynaud phenomenon with episodic arteriolar vasoconstriction of the fingers contributes to pain, ulcer formation, and gangrene. The nails may be shed. Calcium deposits develop in the subcutaneous tissue and erupt through the skin. There may be progression to underlying muscle and bone and other body organs with esophageal involvement being most common.

Suitable clothing and a warm environment are essential to protecting the hands. Trauma and smoking should be avoided.[123] Treatment is individualized and based on severity and progression of the disease. Immunosuppressive medications, ultraviolet light treatment, and other therapies are prescribed.[124,125]

Tick Bites

Ticks are significant vectors of transmitted diseases, including Rocky Mountain spotted fever and other rickettsial diseases, tularemia, Congo-Crimean hemorrhagic fever, and Lyme disease.[126] Ticks vary from 1 cm to about the size of a comma on this printed page. They embed their heads in the skin to obtain blood. As they gorge themselves on blood, they enlarge to many times their normal size and may release toxins or transmit microorganisms during feeding. In most instances, there is no consequence from a tick bite, with the exception of papular urticaria at the site of the bite. If mouthparts remain in the skin when the tick is removed, a persistent nodule remains that may require excision; ideally the tick should be removed completely intact. Irritant substances, such as camphor, soft wax, or heat from a match, may stimulate the tick to withdraw its head. Wearing protective clothing and applying tick repellant, such as diethyltoluamide (DEET), butopyronoxyl (Indalone), or benzylbenzoate, help prevent tick bites.

Lyme disease is a multisystem inflammatory disease caused by the spirochete *Borrelia burgdorferi* transmitted by tick bites and is the most frequently reported vector-borne illness. The highest incidence is among children (50% of infected individuals are symptom free). An immune response to *B. burgdorferi* contributes to the pathogenesis of the disease. The microorganism is difficult to culture and it escapes immunodefenses through antigenetic diversity; blocks complement-mediated killing; impedes release of antimicrobial peptides, leukocyte chemotaxis, and antimicrobial killing; and hides in tissue. It spreads to other tissues by entering capillary beds.[127]

Symptoms of the disease occur in three stages.[128] *Localized infection* occurs soon after the bite (3 to 32 days, the incubation period) with erythema migrans (bull's-eye rash) with or without fever, fatigue, malaise, myalgias, and arthralgias. Erythema migrans is a T-cell–mediated response. Within days to weeks after the onset of the illness, there is *disseminated infection* with secondary erythema migrans, usually with arthralgias, meningitis, neuritis, or carditis. *Late persistent infection* (more common in Europe) can continue for years with arthritis, encephalopathy, polyneuropathy, or heart failure. The diagnosis of Lyme disease is based on the clinical presentation and history of tick bite, if known. Serologic tests may be used to confirm the diagnosis.[129] Antibiotics (e.g., doxycycline [not used in children younger than 8 years or in pregnant or breast-feeding women] or amoxicillin) are used for treatment.[130] Reinfection can occur. There is currently not a vaccine for Lyme disease.[131]

Borrelia miyamotoi also is carried by ticks. The first report of infection was in Russia in 2011 and cases have been confirmed in the United States in areas where Lyme disease is endemic. Serum assays confirm diagnosis. Infected individuals have flu-like symptoms and respond to antibiotic therapy (doxycline or amoxicillin).[132]

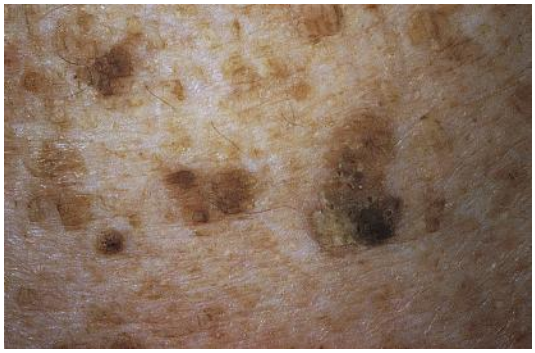

FIGURE 46-24 Seborrheic Keratosis. Typical lesion that is broad, flat, and comparatively smooth surfaced. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-25 Keratoacanthoma. Classic presentation of a fully developed tumor. Round, smooth, dome-shaped mass with a central keratin-filled crater. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Benign Tumors

Most benign tumors of the skin are associated with aging. Benign tumors include seborrheic keratosis, keratoacanthoma, actinic keratosis, and nevi (moles).

Seborrheic Keratosis

Seborrheic keratosis is a benign proliferation of cutaneous basal cells that produces smooth or warty elevated lesions. The pathogenesis is unknown. These tumors are usually seen in older people and occur as multiple lesions on the chest, back, and face. The color varies from tan to waxy yellow, flesh colored, or dark brown-black. Lesion size varies from a few millimeters to several centimeters, and they are often oval and greasy appearing with a hyperkeratotic stuck-on scaly appearance (Figure 46-24). Both cryotherapy with liquid nitrogen and electrocautery are effective treatments, and the lesions usually slough 2 to 3 weeks after treatment.

Keratoacanthoma

A **keratoacanthoma** is a benign self-limiting tumor of squamous cell differentiation arising from hair follicles. It usually occurs on sun-damaged skin of older adults and smokers; the incidence is high in males. The most commonly affected sites are the face, back of the hands, forearms, neck, and legs (Figure 46-25). The lesion develops over a period of 1 to 2 months and

FIGURE 46-26 Actinic Keratosis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

has a histologic course resembling a well-differentiated squamous cell carcinoma as follows:

Proliferative stage: Lesion develops as a rapidly growing, dome-shaped nodule with a central crust.

Mature stage: Lesion fills with whitish keratin and requires differentiation from squamous cell carcinoma.

Involution stage: Occurs over a 3- to 4-month period with regression of the lesion.

Although the lesions resolve spontaneously, they can be removed by curettage or excision to improve cosmetic appearance and reduce risk of destructive growth or a missed diagnosis of squamous cell carcinoma. Intralesional 5-FU, bleomycin, interferon, or methotrexate also have been effective.[133-135]

Actinic Keratosis

Actinic keratosis is a premalignant lesion composed of aberrant proliferations of epidermal keratinocytes caused by prolonged exposure to UV radiation. The prevalence is highest in individuals with unprotected light-colored skin. Actinic keratosis is rare in black skin. The lesions appear as rough or scaly, poorly defined pink to reddish or reddish brown papules that are felt more than seen (Figure 46-26) and are considered an early in situ squamous cell carcinoma. Surrounding areas may have telangiectasia. Dermoscopy and biopsy aid evaluation. Treatment options include ablative and topical therapies, such as 5-FU and imiquimod. The lesions should continue to be evaluated for progressive squamous cell carcinoma. Protection from the sun with clothing or a sunblock to prevent lesions from developing elsewhere is advised.[136]

Nevi

Nevi (moles) are benign pigmented or nonpigmented lesions (Figure 46-27) that form from melanocytes beginning at ages 3 to 5 years. Melanocytic nevus, formed from melanocytes, may be congenital or acquired. During the early stages of development, the cells accumulate at the junction of the dermis and epidermis and are macular lesions. Over time the cells move deeper into the dermis and the nevi become nodular and symmetric without irregular borders. Nevi may appear on any part of the skin, and vary in size. They occur singly or in groups and

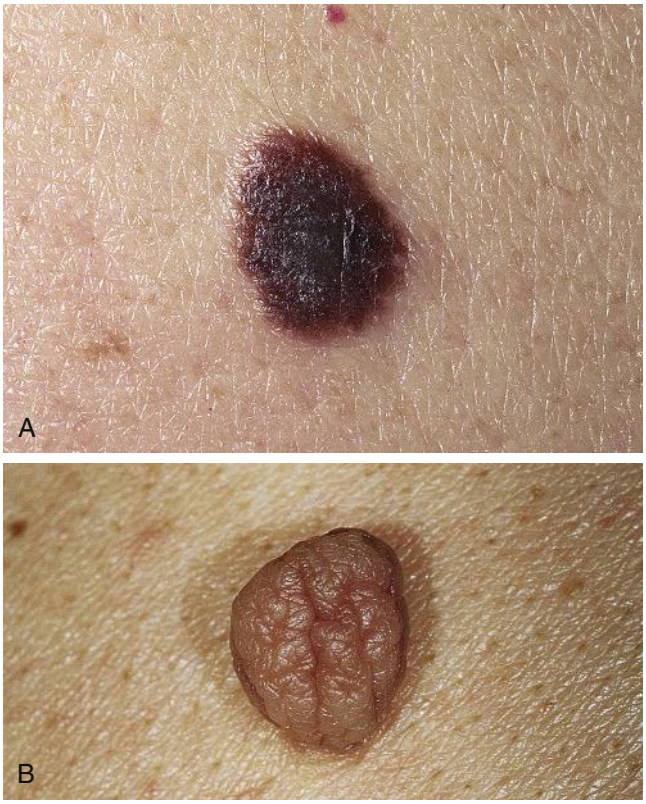

FIGURE 46-27 Nevi. **A,** Junction nevus: slightly raised, dark, and uniform. **B,** Dermal nevus: pedunculated with a soft, flabby, wrinkled surface. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, Philadelphia, 2010, Mosby.)

are not considered disfiguring. Nevi may undergo transition to malignant melanomas (see p. 1643).[137] Nevi repeatedly traumatized, irritated by clothing, or considered too large can be excised.

Skin Cancer

Basal cell carcinoma and squamous cell carcinoma are the most prevalent forms of cancer. Malignant melanoma is the most serious and the most common cause of death from skin cancer.[138] Important trends related to skin cancer are presented in Box 46-4.

Chronic ultraviolet (UV) radiation causes most skin cancers. Protection from UV radiation from the sun and artificial sources (e.g., tanning beds), particularly during the childhood years, significantly reduces the risk of skin cancer in later years. Areas commonly exposed to the sun's rays—face, neck, and hands—are highly vulnerable for such lesions. Dark-skinned persons and those avoiding sunlight are significantly less likely to develop these malignant tumors. In dark-skinned persons, basal cells contain the pigment melanin, a protective factor against sun exposure.

Basal Cell Carcinoma

Basal cell carcinoma is a surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells. The tumors grow upward and laterally or downward to the

BOX 46-4 IMPORTANT TRENDS FOR SKIN CANCER

Incidence
More than 3.5 million cases per year with likely underreporting because of lack of a non–melanoma skin cancer registry
Greater in women younger than age 40 years; greater in men after age 40 years; 40 times more prevalent in whites than in blacks; increases steadily with age; increasing among young individuals with chronic exposure to artificial UV radiation
Majority of cases are highly curable **basal** or **squamous** cell cancers and the most serious is **malignant melanoma** with an estimated 76,690 new cases in 2013; it represents 4% of all skin cancer cases but causes about 79% of all skin cancer deaths

Mortality
Total estimated deaths in 2013 were 9480 from melanoma and approximately 3170 from other nonepithelial types of skin cancer

Risk Factors
Excessive exposure to ultraviolet radiation from the sun
Exposure to artificial UV radiation, particularly in ages less than 25 years
Fair complexion, blue eyes, blonde hair
Occupational exposure to coal tar, pitch, creosote, arsenic compounds, and radium
Exposure to human papillomavirus and human immunodeficiency virus
Immunosuppression
Family history of skin cancer
Skin cancer is negligible in blacks because of heavy skin pigmentation

Warning Signals
Any change on the skin, especially a change in the size or color of a mole or other darkly pigmented growth or spot

Prevention and Early Detection
Avoidance of artificial UV radiation and sun when ultraviolet light is strongest (e.g., 10 AM to 3 PM); use of protective clothing and sunscreen preparations, especially those containing ingredients such as *para*-aminobenzoic acid (PABA); prevention for all types of skin cancer should begin in childhood

Survival
For basal cell and squamous cell cancers, cure is highly likely with early detection and treatment; malignant melanoma metastasizes quickly, accounting for a lower 5-year survival rate

Data from American Cancer Society: *Cancer facts and figures 2013,* Atlanta, 2013, The Society; Rogers HW et al: *Arch Dermatol* 146(3):283–287, 2010; Wehner MR et al: *BMJ* 345:e5909, 2012.

dermal-epidermal junction. They usually have depressed centers and rolled borders. Early tumors are so small that they are not clinically apparent.

Basal cell carcinoma is the most common type of skin cancer in whites and is thought to be caused by UV radiation exposure. It also is associated with arsenic from groundwater wells[139] and autosomal dominant nevoid basal cell carcinoma syndrome. Basal cell carcinoma arises from mutation in the *TP53* tumor-suppressor gene, leading to loss of keratinocyte repair functions and apoptosis resistance of DNA-damaged cells. Other oncogenic pathways include mutation in the *PTCH1* gene that has tumor-suppressor activity, and alteration in the Sonic Hedgehog signaling pathway genes (codes for a protein important for cell growth and differentiation).[140]

Lesion subtypes include superficial, nodular, and sclerosing/morpheaform, which can be pigmented or nonpigmented (Figure 46-28). Early tumors are so small that they are not clinically apparent. The lesion often begins as a nodule (greater than 5 mm across) that is pearly or ivory in appearance and slightly elevated above the skin surface with small blood vessels on the surface (telangiectasias). The tumors grow upward and laterally or downward to the dermal-epidermal junction. They usually have depressed centers and rolled borders. As the lesion grows, it often ulcerates, develops crusting, and becomes firm to the touch. If left untreated basal cell lesions invade surrounding tissues and, over months or years, can destroy a nose, an eyelid, or an ear. Metastatic spread is rare because these tumors do not invade blood or lymph vessels. Treatment includes complete surgical excision, radiotherapy, curettage, cryotherapy, photodynamic therapy, and topical applications of imiquimod or 5-fluorouracil.[140]

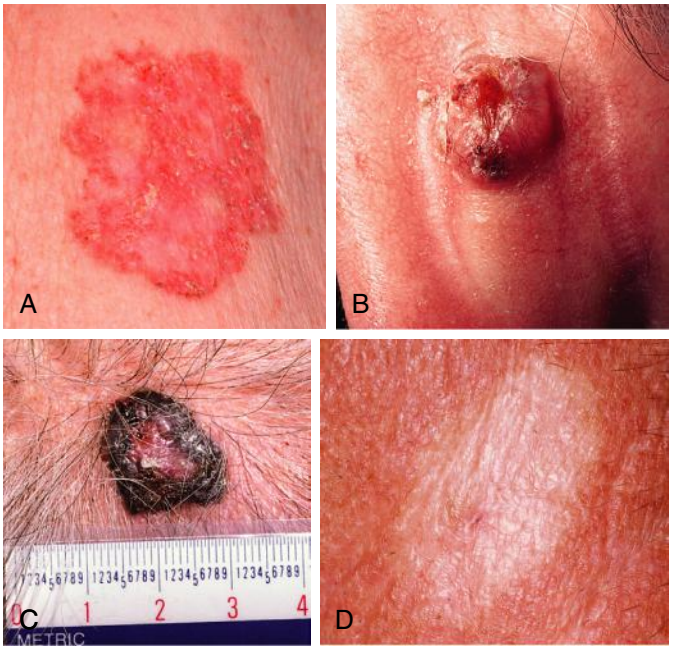

FIGURE 46-28 Types of Basal Cell Carcinoma. **A,** Superficial. **B,** Nodular. **C,** Pigmented. **D,** Morpheaform—recurrent tumor. (**A** and **D** from Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* ed 3, Philadelphia, 2012, Saunders; **B** and **C** from James WD, Berger TG, Elston DM: *Andrews' diseases of the skin: clinical dermatology,* ed 11, Philadelphia, 2011, Saunders.)

Squamous Cell Carcinoma

Squamous cell carcinoma (**SCC**) is a tumor of the epidermis and the second most common human cancer. Two types are characterized: in situ (Bowen disease [BD]) and invasive. Areas affected are the head and neck (75%) and the hands (15%), with 10% of squamous cell carcinomas occurring elsewhere on the body. These tumors are more predominant in countries where arsenic is found in higher rates in drinking water. UV light exposure from sun and the use of tanning beds are the primary risk factors. Gamma rays and x-rays are also associated

FIGURE 46-29 Squamous Cell Carcinoma. The sun-exposed ear is a common site for squamous cell carcinoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

with squamous cell carcinoma. In addition, patients who are immunosuppressed experience a greater occurrence of this carcinoma.

UV exposure causes SCC, particularly mutation of the *TP53* gene and other oncogenic signals.[141] It is unclear how UV light produces alterations in DNA, and DNA repair. Invasive SCC can arise from premalignant lesions of the skin. It rarely arises from normal-appearing skin or de novo. The premalignant lesions include sun-damaged skin or dysplasias (actinic keratosis); leukoplakia, or whitish, discolored areas; scars; radiation-induced keratosis; tar and oil keratosis; and chronic ulcers and sinuses.

In situ SCC is usually confined to the epidermis (intraepidermal) but may extend into the dermis. Common premalignant skin lesions associated with in situ squamous cell carcinomas are actinic (solar) keratosis and BD. Actinic keratosis is a white, scaly, keratotic (horny) lesion on the exposed areas of the body (see Figure 46-26). BD is a dysplasia of the basal layer of the dermis or carcinoma in situ. It often is found on unexposed areas of the body and is demonstrated by flat, reddish, scaly patches. These lesions may enlarge to more than 1 cm in diameter, rarely invading surrounding tissue and very rarely metastasizing. Other cellular components in the skin (e.g., sweat glands, hair follicles) can give rise to SCC but these cancers are relatively uncommon. Invasive SCC grows more rapidly than basal cell carcinomas and can spread to regional lymph nodes with metastasis. These tumors are firm and increase in elevation and diameter. The surface may be granular and bleed easily (Figure 46-29). Treatment includes surgical excision and radiotherapy with consideration of adjuvant chemotherapy for advanced disease.[142] Mohs micrographic surgery (MMS), a tissue-sparing surgical technique, is indicated for non-melanoma skin cancers (NMSCs) with a high risk of recurrence, lesions involving the face, ears, genitalia, or when wider excision may risk functional impairment.[142a]

Cutaneous Melanoma

Cutaneous melanoma is a malignant tumor of the skin originating from melanocytes, or cells that synthesize the pigment melanin. The incidence of melanoma is increasing, and young to middle-age adults are at highest risk. Risk factors implicated in melanoma induction include genetic predisposition, exposure to ultraviolet light (solar and artificial), acquired melanocytic nevi, family history of melanoma, fair hair, light skin with a propensity to sunburn, and the presence of susceptibility genes (e.g., *BRAF* and *RAS* mutations).[143,144] Specific genetic alterations are associated with particular clinical and histopathologic features of the disease.[145]

TABLE 46-9 CLASSIFICATION OF NEVI

NEVI	COMMON CHARACTERISTICS
Junctional nevus	Flat, well circumscribed, vary in size up to 2 cm, dark color, hairs may be present; originate in basal layer of epidermis and can eventually reach the cutaneous surface; rarely develop into a melanoma
Compound nevus	Most common in adolescents; the majority of pigmented lesions are in children; rarely develops into melanoma; usually 1 cm in size; hairs may be present; surface is elevated and smooth
Intradermal nevus	Small (less than 1 cm) with regular edges and bristle-like hairs; color ranges from skin tone to light brown; has a slight likelihood of developing into a melanoma

The relationship between nevi (see Figure 46-27) and melanoma makes it important for the clinician to understand the various neval forms (Table 46-9). Most nevi never become suspicious; however, suspicious nevi should be evaluated and removed. Indications for biopsy include changes in color and size, irregular notched margin, itching, bleeding or oozing, nodularity, scab formation, ulceration, or an unusual pattern of presentation. The ABCDE rule is used as a guide: **A**symmetry, **B**order irregularity, **C**olor variation, **D**iameter larger than 6 mm, and **E**levation, which includes raised appearance or rapid enlargement.[146] Clinical characteristics are summarized in Table 46-10.

Melanomas arise as a result of malignant degeneration of melanocytes located either along the basal layer of the epidermis or in a benign melanocytic nevus. The clinical types of cutaneous melanoma are based on their growth pattern and include lentigo malignant melanoma (LMM) (Figure 46-30), superficial spreading melanoma (SSM) (the most common), primary nodular melanoma (PNM), and acral-lentiginous melanoma. Rare and difficult to diagnose subtypes include desmoplastic melanoma, which resembles a scar, and amelanotic (nonpigmented) melanoma.[147] The pathogenesis of malignant melanoma is complex and a number of proto-oncogenes have been identified.[148]

Surveillance strategies include clinician-based total body skin examination, total body photography, dermoscopy, and individual-based self-skin examination. Detection of volatile biomarkers are in development.[148a] Staging of melanoma is determined using tumor, node, metastasis (TMN) criteria established by the American Joint Committee on Cancer and is summarized in Box 46-5.

Prognostic factors include the thickness of the lesion, mitotic index, immunohistochemical assessment, ulceration and metastasis (e.g., number of lymph nodes or viscera involved).[149]

TABLE 46-10 CLINICAL CHARACTERISTICS OF VARIETIES OF CUTANEOUS MELANOMA

CHARACTERISTIC	DESCRIPTION
Lentigo Malignant Melanoma	
Frequency	4% to 15% of cutaneous melanomas
Age at diagnosis	50 to 80 years old, mean age 65 years
Primary location	Head, neck, dorsum of hands (sun-exposed areas)
Pigmentation according to thickness	
<1.5 mm (levels I and II)	Tan and brown
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Superficial Spreading Melanomas	
Frequency	57% to 70% of cutaneous melanomas
Age at diagnosis	20 to 60 years old
Primary location	Legs of females; upper back of both genders
Pigmentation according to thickness	
<1.5 mm (levels I and II)	Tan and brown
>1.5 mm (level III)	Tan, brown, and blue-black
>1.5 mm (levels IV and V)	Nodule formation
Primary Nodular Melanoma	
Frequency	12% to 21% of cutaneous melanomas
Age at diagnosis	20 to 60 years old, mean age 53 years
Primary location	Trunk, head, or neck
Pigmentation according to thickness	
>1.5 mm (level III)	Small nodule (any hue)
>1.5 mm (levels IV and V)	Large nodule (any hue)
Acral-Lentiginous Melanoma	
Frequency	2% to 8% in whites; 30% to 75% in blacks, Hispanics, Asians
Age at diagnosis	20 to 60 years old
Primary location	Palms, soles of feet, mucous membranes
Pigmentation at any thickness	Blue-black irregular macules, papules, or nodules

Data from Bolognia JL, Jorizzo JL, Schaffer JV: *Dermatology,* ed 3, Philadelphia, 2012, Saunders; Greenwald HS, Friedman EB, Osman I: *Melanoma Res* 22(1):1–8, 2012; Habif TP, editor: *Clinical dermatology,* ed 5, St Louis, 2010, Mosby; Scolyer RA, Long GV, Thompson JF: *Mol Oncol* 5(2):124–136, 2011; Situm M, Buljan M: *G Ital Dermatol Venereol* 147(1):21–27, 2012.

BOX 46-5 TNM STAGING CRITERIA FOR MELANOMA

Stage 0: carcinoma in situ (TisN0M0)
Stage I A/B: includes lesions up to 2 mm with no nodal or distant metastases (T1aN0M0, T1bN0M0, T2aN0M0).
Stage II A/B/C: includes larger lesions, greater than 2 mm without positive nodes or distant metastases (T2bN0M0, T3aN0M0, T3bN0M0, T4aN0M0, T4bN0M0).
Stage III: includes lesions of any size with positive lymph nodes (TxN1M0, TxN2M0, TxN3M0).
Stage IV: includes lesions of any size with distant metastases (TxNxM1).

Data from Piris A, Lobo AC, Duncan LM: Melanoma staging: where are we now?, *Dermatol Clin* 30(4):581–592, v, 2012.

FIGURE 46-30 Lentigo Malignant Melanoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 46-31 Nodular Melanoma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Figure 46-31 illustrates a nodular melanoma. Efforts are in progress to refine the morphologic classifications by adding subgroups that include molecular markers for proto-oncogene mutations and specific signaling pathways.[150] Early recognition of cutaneous melanomas can have a major effect on achieving a surgical cure.

Prevention of melanoma includes avoidance of UV radiation exposure through use of protective clothing and sunscreens, and avoidance of artificial UV radiation exposure. Treatment of melanoma with no evidence of metastatic disease involves surgical excision to the primary site and regional lymph nodes. The extent of surgery is determined by the staging of disease. Lesions of the extremities have the best prognosis; head and neck lesions and trunk lesions have the poorest prognosis. Survival rate for advanced disease is very low. Immunotherapy is advancing. Ipilimumab blocks cytotoxic T-lymphocyte antigen 4 and vemurafenib has prolonged survival with *BRAF*-mutated melanoma, and new drugs are in clinical trials. Improving response and survival rates with novel cellular targets and combination therapies to overcome tumor resistance is an ongoing need.[151,152] Vaccines, biomarkers, and genetically-modified T cells are under investigation.[153,154]

FIGURE 46-32 Kaposi Sarcoma. The purple lesion commonly seen on the skin. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Kaposi Sarcoma

Kaposi sarcoma (KS) is a vascular malignancy associated with different presentations: (1) drug-induced immunosuppressions, for example, after kidney transplantation; (2) an endemic form in equatorial Africa; (3) classic form presenting on the lower legs of older men; (4) epidemic and nonepidemic forms related to acquired immunodeficiency syndrome (AIDS), and (5) iatrogenic.[155]

Kaposi-associated herpesvirus 8 (HHV-8) is found in all forms of KS and may be a common etiology for all types of KS in combination with host immune dysfunction and the local inflammatory state.[155] Immunosuppression allows for opportunistic infections and malignancy. Proliferation of the tumor depends on the presence of platelet-derived and other growth factors.[156]

The endothelial cell is thought to be the progenitor of KS but the specific origin is elusive. The lesions emerge as purplish brown macules and develop into plaques and nodules. They tend to be multifocal rather than spreading by metastasis. The lesions initially appear over the lower extremities in the classic form (Figure 46-32). The rapidly progressive form associated with AIDS tends to spread symmetrically over the upper body, particularly the face and oral mucosa. The lesions are often pruritic and painful. About 75% of individuals with epidemic KS have involvement of lymph nodes, particularly in the gastrointestinal tract and lungs. Organ involvement is much less common in the classic form. The rapidly progressive form has a poor prognosis and shorter survival rates than the classic form. (See Chapter 10 for a further discussion on AIDS.)

Diagnosis is by skin biopsy, with a high index of suspicion for those with immunodeficiency. The disease is incurable. Local lesions can be excised. Multiple disseminated lesions may be treated with a combination of immunomodulatory, cytotoxic, and antiviral drugs. The new, highly active antiretroviral therapy (HAART) for AIDS treatment is decreasing the incidence of KS in resource rich countries, but new treatments are needed.[157]

Primary Cutaneous Lymphomas

Primary cutaneous lymphomas are cutaneous T-cell and B-cell lymphomas that are present in the skin without evidence of extracutaneous disease at the time of diagnosis (see Chapter 29 for classification and general pathophysiology of lymphomas). Cutaneous lymphomas are rare but are the second most common site of extranodal non-Hodgkin lymphoma. The incidence rate is about 14/100,000 and their cause is unknown.[158] Cutaneous lymphomas are more common in men and generally present after age 50 years; 75% of cases are T-cell lymphomas and 25% are B-cell lymphomas. The most common cutaneous T-cell lymphoma is mycosis fungoides (50% of cases), which is more common among blacks. Sézary syndrome (a leukemic variant of T-cell lymphoma) and primary cutaneous CD30-positive lymphoproliferations (less than 10% of cases) are the most aggressive. Cutaneous lymphomas develop from clonal expansion of B cells, T helper cells, and rarely T suppressor cells. **Mycosis fungoides** can present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors (Figure 46-33). There may be patches of alopecia. The lesions progress over a period of months or years. Mycosis fungoides lesions are pruritic and cause considerable distress and debilitation.[159] Involvement of other organs can occur in advanced stages of the disease.

FIGURE 46-33 Mycosis Fungoides. **A,** Hypopigmented patches of mycosis fungoides. **B,** Plaques of mycosis fungoides. **C,** Tumors of mycosis fungoides combined with patches. (Courtesy of Ellen Korn, M.D. In James WD, Berger TG, Elston DM: *Andrews' diseases of the skin: clinical dermatology,* ed 11, Philadelphia, 2011, Saunders.)

The differential diagnosis of the different types of cutaneous lymphomas is based on clinical manifestations, histologic appearance, immunologic and cytogenetic features, and response to appropriate treatment.[160,160a] Lesions also must be distinguished from psoriasis, eczema, generalized dermatitis, and drug reactions. Treatment is based on staging of the disease following consensus-based guidelines that include a range of topical and systemic therapies, such as anti-inflammatory, immunomodulatory, and biologic agents; histone deacetylase inhibitors; rexinoids; and chemotherapeutics.[161,162] Radiotherapy has historically been the most common successful therapy.[163]

Cold Injury

Exposure to extreme cold includes a spectrum of injuries[164]:

1. *Frostnip*—mild and completely reversible injury characterized by skin pallor and numbness
2. *Chilblains*—more serious injury with violaceous skin color with plaques or nodules, pain, and pruritus but without ice crystal formation; a chronic vasculitis can develop and is usually located on the face, anterior lower leg, hands, and feet
3. *Frostbite*—tissues freeze and form ice crystals at temperatures below −2° C (28° F), progressing from distal to proximal; is potentially reversible
4. *Flash freeze*—rapid cooling with intracellular ice crystals associated with contact with cold metals or volatile liquids

Areas most commonly affected are fingers, toes, ears, nose, and cheeks. Initially the body responds with alternating cycles of vasoconstriction and vasodilation—the "hunting reflex." The mechanism of injury is complex but is related to direct cold injury to cells, indirect injury, cell death from extracellular and intracellular ice crystal formation, impaired circulation with anoxia because of thrombosis in the exposed area, and reperfusion injury. With tissue reperfusion there is infiltration of neutrophils and mast cells and these cells and the damaged epithelium release inflammatory mediators (e.g., prostaglandins, thromboxanes, bradykinin, and histamine). Edema can cause capillary compression and vascular stasis. Frozen skin becomes white or yellowish, waxy, and firm to the touch. There is numbness and no sensation of pain.

Skin damage can range from mild to severe. With mild frostbite, redness and discomfort occur during rewarming, followed by a return to normal in a few hours. In more severe cases, cyanosis and mottling develop, followed by redness, swelling, throbbing, and burning pain on rewarming. Within 24 to 48 hours, vesicles and bullae appear and resolve into crusts that eventually slough off, leaving thin, newly formed skin. The most severe cases result in gangrene with loss of the affected part. Frostbite may be classified by depth of injury after rewarming as follows:

First degree: superficial, characterized by a numb central white area surrounded by erythema and edema and including partial skin freezing without blistering

Second degree: full-thickness skin freezing with blistering surrounded by edema and hyperemia

Third degree: deep, characterized by full-thickness skin and subcutaneous freezing with tissue necrosis and hemorrhagic vesicles and blisters

Fourth degree: deep tissue freezing with full-thickness necrosis and gangrene with a line of demarcation.

Immediate treatment of frostbite is to cover affected areas with other body surfaces and warm clothing. The area should not be rubbed or massaged. Local, dry heat should be avoided. Immersion in a warm water bath (40° to 42° C [104° to 107.6° F]) until frozen tissue is thawed is the best treatment. Ibuprofen is used to inhibit prostaglandins, and aloe vera is a topical inhibitor of thromboxane. Thrombolytic therapy reduces the incidence of amputation when administered within 24 hours of injury.[165]

Pain during the thawing period is severe and should be treated with potent analgesics. Gentle cleansing and no pressure on the skin should be maintained during healing. Amputation of necrotic tissue is delayed until a clear line of demarcation is established.[166]

DISORDERS OF THE HAIR

Alopecia

Male-Pattern Alopecia (Androcentric Alopecia)

Alopecia means loss of hair. Localized hair loss in men is not a disease but rather a variation in the androgen receptor *(AR)* gene that clusters in families. The mechanism of inheritance is unknown. Within the distribution of hair over the scalp, androgen-sensitive hair follicles are on top and androgen-insensitive follicles are on the sides and back. In genetically predisposed men, the androgen-sensitive follicles are transformed into vellus follicles. The normal hair is shed and replaced by fine, light, short hair. Male-pattern baldness begins with frontotemporal recession and progresses to loss of hair over the top of the scalp. Minoxidil may be used to stimulate hair growth and finasteride may decrease the effect of androgens on hair follicles. New treatments are being evaluated.[167] Affected men may choose to wear wigs or have hair transplants.

Female-Pattern Alopecia

Women in their twenties and thirties (6% to 12%) and women older than 70 years (55%) experience progressive thinning and loss of hair over the central part of the scalp. Contrary to male-pattern baldness, no loss of hair occurs along the frontal hairline but follicles are smaller and less functional. Many of these women have elevated levels of serum adrenal androgen dehydroepiandrosterone sulfate (DHEAS), and treatment with antiandrogens can be effective. Lower levels of estrogen can also decrease hair growth after menopause. Finasteride, minoxidil, light therapy or combinations of therapy may be used and work best when started early.[168,169] In rare instances a male-pattern baldness develops. Laboratory evaluation of serum androgenic hormones shows elevations, and some women have decreased hair loss when treated with daily doses of spironolactone.

Alopecia Areata

Alopecia areata is an autoimmune T-cell–mediated chronic inflammatory disease directed at hair follicles that results in baldness. Hair loss occurs in multiple areas of the scalp, usually in round patches. The eyebrows, eyelashes, beard, and other areas of the body are rarely involved. The cause is unknown, but stressful events, cell-mediated immune factors, and genetic susceptibility are linked to hair loss.[170] Metabolic disorders, such as Addison disease, thyroid disease, and lupus erythematosus, also are associated with alopecia areata.[171]

The affected areas of skin are smooth or may have short shafts of poorly developed hair that breaks at the surface. Regrowth occurs within 1 to 3 months, but hair loss may recur at the same site. Permanent regrowth of hair usually occurs. Total loss of hair (alopecia totalis) occurs in some young people; the long-term prognosis for total hair regrowth is poor.

Diagnosis is made by observation of the pattern of hair loss. Biopsy may show a lymphocytic infiltrate around the follicle. There are several treatments for alopecia areata including watchful waiting, corticosteroids, minoxidil, and topical immunotherapy.[172]

Hirsutism

Hirsutism is the abnormal growth and distribution of hair on the face, body, and pubic area in a male pattern that occurs in women. There is also frontotemporal hair recession. These areas of hair growth are androgen sensitive. Variations of hair growth in women are great, and a male pattern can be normal. Women who develop hirsutism may be secreting hormones associated with ovarian or adrenal disease, and such women should be evaluated for polycystic ovaries, adrenal hyperplasia, or adrenal tumors.[173] If no hormonal pathologic conditions exist, undesirable hair can be mechanically removed. Endocrine therapy to suppress androgens may be considered.[174]

DISORDERS OF THE NAIL

Paronychia

Paronychia is an acute or chronic infection of the cuticle.[175] Acute paronychia is manifested by the rapid onset of painful inflammation of the cuticle, usually after minor trauma. An abscess may develop, requiring incision and drainage (I&D) for relief of pain. The most common causative microorganisms are *Staphylococci, Streptococci,* and occasionally *Candida*.

Chronic paronychia develops slowly, with tenderness and swelling around the proximal or lateral nail folds. One or more fingers or toes may be involved. Individuals whose hands are frequently exposed to moisture are at greatest risk. Manipulation or chronic wetting of the cuticle increases risk because it disrupts the natural protective barrier provided by the cuticle, leaving a moist, warm medium for pathogenic microorganisms to incubate. The skin around the nail becomes more edematous and painful with progressive infection. Pus may be expressed from the proximal nail fold. The nail plate is usually not affected, although it can become discolored and develop ridges with chronic infections.

Treatment includes keeping the hands dry. Abscesses are treated with incision and drainage; severe bacterial cases may require systemic antibiotics. Oral antifungals are not very effective because they do not penetrate the affected tissues but efficacy is increased with topical application of steroid creams.[175]

Onychomycosis

Onychomycosis is a fungal or dermatophyte infection of the nail plate that occurs in 2% to 18% of the population.[176] The most common pattern is a nail plate that turns yellow or white (infection develops from the dorsal surface) and becomes elevated as a result of the accumulation of hyperkeratotic debris within the plate. Fungal infections of the nail may require culture and microscopy. Treatment includes débridement and systemic antifungal therapy. Surgical excision of the nail may be required. New systemic and topical antifungals are being investigated.[177]

SUMMARY REVIEW

Structure and Function of the Skin

1. The skin is the largest organ of the body and equals about 20% of body weight.
2. The skin has three layers: the dermis, epidermis, and subcutaneous layer.
3. Keratinocytes produce keratin to form the superficial layer of the epidermis. The underlying epidermis contains a basal and a spinous layer with melanocytes, Langerhans cells, and Merkel cells.
4. The dermis is composed of connective tissue elements, hair follicles, sweat glands, sebaceous glands, blood vessels, nerves, and lymphatic vessels.
5. The subcutaneous layer contains fat cells and connective tissue.
6. The dermal appendages include the nails, hair, sebaceous glands, and the eccrine and apocrine sweat glands.
7. The papillary capillaries provide the major blood supply to the skin, arising from deeper arterial plexuses. The sympathetic nervous system regulates skin blood flow.
8. Heat loss and heat conservation are regulated by arteriovenous anastomoses that lead to the papillary capillaries.
9. Older skin is thinner and drier with less collagen; it has fewer capillary loops and fewer changes in pigmentation.
10. Loss of melanocytes and hair follicles leads to gray and thinner hair.
11. The skin of older adults is more permeable; there is decreased sweating and loss of thermal regulation and decreased protective functions.
12. Pressure ulcers develop from continuous pressure and shearing forces that occlude capillary blood flow with resulting ischemia and necrosis. Areas at greatest risk are pressure points over bony prominences, such as the greater trochanter, sacrum, ischia, and heels. Immobilized individuals with fractures and neurologic deficits are most likely to develop pressure ulcers.
13. Keloids are scars that extend beyond the border of injury and result from abnormal fibroblast activity and excess collagen formation. Hypertrophic scars are elevated erythematous fibrous lesions that do not expand beyond the border of injury.
14. Pruritus (itching) is associated with many skin disorders. Itch mediators, peripheral polymodal C nerve fibers, and central processes contribute to itching. Scratching can cause skin trauma, infection, and scarring.

Disorders of the Skin

1. Allergic contact dermatitis is a form of delayed hypersensitivity that develops with sensitization to allergens, such as metals, chemicals, or poison ivy.

SUMMARY REVIEW—cont'd

2. Irritant contact dermatitis develops as an inflammatory response to prolonged exposure to chemicals, such as acids or soaps.
3. Atopic or allergic dermatitis is associated with a family history of allergies, hay fever, elevated IgE levels, and increased histamine sensitivity; it is more common in children.
4. Stasis dermatitis occurs on the legs and results from venous stasis and edema.
5. Seborrheic dermatitis involves scaly, yellowish, inflammatory plaques of the scalp, eyebrows, eyelids, ear canals, chest, axillae, and back. The cause is unknown.
6. Papulosquamous disorders are characterized by papules, scales, plaques, and erythema.
7. Psoriasis is a chronic autoimmune T-cell–mediated inflammatory skin disease with thickening of the epidermis and dermis characterized by scaly, erythematous pruritic plaques. The forms of psoriasis are plaque, inverse, guttate, pustular, and erythrodermic. Systemic complications can accompany the disease including arthritis and cardiovascular disease.
8. Pityriasis rosea is a self-limiting disease characterized by oval lesions with scales around the edges located along skin lines of the trunk.
9. Lichen planus is a papular violet-colored autoimmune inflammatory lesion involving T cells and inflammatory cytokines manifested by severe pruritus and can involve both skin and mucous membrane lesions.
10. Acne vulgaris is a facial inflammation of the pilosebaceous follicles with hypertrophy of sebaceous glands and telangiectasia, particularly of the nose.
11. Acne rosacea develops on the middle third of the face with hypertrophy and inflammation of the sebaceous glands that may be the result of infection or immune-mediated inflammation.
12. Lupus erythematosus is an inflammatory autoimmune disease that can affect only the skin (discoid) or have a systemic presentation. The inflammatory lesions usually occur in sun-exposed areas with a butterfly distribution over the nose and cheeks.
13. Pemphigus is a chronic, autoimmune, blistering disease that begins in the mouth or on the scalp and spreads to other parts of the body, often with a fatal outcome. The forms of pemphigus include pemphigus vulgaris (most common), pemphigus foliaceus, paraneoplastic pemphigus, and IgA pemphigus.
14. Bullous pemphigoid is a benign autoimmune blistering disease that resolves rapidly.
15. Erythema multiforme is an acute inflammation of the skin and mucous membranes with lesions that appear target-like with alternating rings of edema and inflammation; it is often associated with allergic reactions to drugs.
16. Folliculitis is a bacterial infection of the hair follicle.
17. A furuncle is an infection of the hair follicle that extends to the surrounding tissue.
18. A carbuncle is a collection of infected hair follicles that forms a draining abscess.
19. Cellulitis is a diffuse infection of the dermis and subcutaneous tissue.
20. Erysipelas is a superficial streptococcal infection of the skin commonly affecting the face, ears, and lower legs.
21. Impetigo may have a bullous or an ulcerative form and is caused by *Staphylococcus* or *Streptococcus* and is more common in children.
22. HSV-1 causes cold sores but can infect the cornea, mouth, and labia. HSV-2 causes genital lesions and is usually spread by sexual contact.
23. Herpes zoster and varicella (chickenpox) are both caused by the same herpesvirus, with herpes zoster manifesting years after the initial infection.
24. Warts (verrucae) are benign, rough, elevated lesions caused by papillomavirus. Venereal warts (condylomata acuminata) are spread by sexual contact.
25. Tinea skin infections (fungal infections) can occur anywhere on the body and are classified by location (i.e., tinea pedis, tinea corporis, tinea capitis).
26. Candidiasis is a yeastlike fungal infection caused by *C. albicans* occurring on skin, on mucous membranes, and in the gastrointestinal tract.
27. Cutaneous vasculitis is an immune-mediated inflammation of skin blood vessels with purpura, ischemia, and necrosis resulting from vessel necrosis.
28. Urticarial lesions are associated with type I hypersensitivity responses and appear as wheals, welts, or hives.
29. Localized scleroderma is an immune-mediated sclerosis of the skin that also may affect muscle, bone, and other body organs.
30. Ticks cause a local reaction on the skin of humans and can cause systemic disease when mouthparts pierce the skin and remain embedded in the tissue.
31. Lyme disease is a multisystem inflammatory disease caused by *B. burgdorferi* transmitted by tick bites. Complications may persist for years.
32. Seborrheic keratosis is a proliferation of squamous cells that produce elevated, smooth, or warty lesions of varying size usually in sun-damaged skin. They are most common among older adults.
33. Keratoacanthoma arises from hair follicles on sun-exposed areas. There are three stages of development that result in a dome-shaped, crusty lesion filled with keratin that resolves in 3 to 4 months.
34. Actinic keratosis is a pigmented scaly lesion that develops in sun-exposed individuals with fair skin. The lesion may become malignant in the form of squamous cell carcinoma.
35. Nevi arise from melanocytes and may be pigmented or fleshy pink. They occur singly or in groups and may undergo transition to malignant melanoma.
36. Basal cell carcinoma is the most common skin cancer and occurs most often on sun-exposed areas.

SUMMARY REVIEW—cont'd

37. Squamous cell carcinoma is a tumor of the epidermis associated with sun exposure and can be localized (in situ) or invasive.
38. Cutaneous melanoma arises from melanocytes; if it is not excised early, metastasis occurs through the lymph nodes.
39. KS is a vascular malignancy associated with immunodeficiency states and is associated with herpesvirus 8.
40. Cutaneous lymphomas are cutaneous T-cell and B-cell lymphomas that are present in the skin without evidence of extracutaneous disease at the time of diagnosis.
41. Frostbite usually occurs on cheeks and digits, causing direct injury to cells and impaired circulation.

Disorders of the Hair

1. Male-pattern alopecia is an inherited form of irreversible baldness with hair loss in the central scalp and recession of the temporofrontal hairline.
2. Female-pattern alopecia is a thinning of the central hair of the scalp beginning in women at 20 to 30 years of age.
3. Alopecia areata is patchy loss of hair associated with an autoimmune process and triggered by stress or metabolic diseases; it is usually reversible.
4. Hirsutism is a male pattern of hair growth in women that may be normal or the result of excessive secretion of androgenic hormones.

Disorders of the Nail

1. Paronychia is an inflammation of the cuticle that can be acute or chronic and is usually caused by staphylococci or streptococci.
2. Onychomycosis is a fungal infection of the nail plate.

Children often develop alterations in the skin that may be minor or severe and localized or generalized. Skin diseases in children may have a different causative mechanism of expression than those found in adults, although there may be similarities. Diagnosis is commonly made from the history, appearance, and distribution of the lesion or lesions. Common skin diseases of childhood are presented here.

ACNE VULGARIS

Acne vulgaris is the most common skin disease and affects 85% of the population between the ages of 12 and 25 years. Onset is occurring at a younger age and may be associated with earlier onset of puberty in the United States. Genetic influences may determine an individual's susceptibility and severity of disease. Severe acne tends to have a genetic predisposition.[1] The incidence of acne is the same in both genders, although severe disease affects males more often.

Acne develops at distinctive pilosebaceous units, known as *sebaceous follicles*. Located primarily on the face and upper parts of the chest and back, these follicles have many large sebaceous glands, a small vellus hair (very short, nonpigmented, and very thin hair), and a dilated follicular canal that is visible as a pore on the skin surface. Acne lesions may be inflammatory (pustules, papules, nodules) or noninflammatory. In **noninflammatory acne** the comedones are open (blackheads) and closed (whiteheads), with the accumulated material causing distention of the follicle and thinning of follicular canal walls. **Inflammatory acne** develops in closed comedones when the follicular wall ruptures, expelling sebum into the surrounding dermis and initiating inflammation. Pustules form when the inflammation is close to the surface; papules and cystic nodules can develop

FIGURE 47-1 Cystic Acne. Multiple pustules (erythematous papules and pustules) are present, and several have become confluent. Note areas of scarring. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

when the inflammation is deeper, causing mild to severe scarring (Figure 47-1). Many types of lesions may exist in the same individual.

The exact cause of acne is unknown and various pathophysiologic factors contribute to the development of acne. The principal factors are follicular hyperkeratinization, excessive sebum production, follicular proliferation of *Propionibacterium acnes,* and inflammation and rupture of a follicle from accumulated debris and bacteria within the follicle. Androgens (dihydrotestosterone and testosterone) synthesized in increasing amounts during puberty boost the size and productivity of the sebaceous glands and promote *P. acnes*. Acne also is associated with polycystic ovarian syndrome, congenital adrenal hyperplasia, and various endocrine tumors as a result of higher circulating levels of androgens. The *P. acnes* anaerobic bacteria produce extracellular porphyrins and proinflammatory molecules, including chemotactic factors and lipolytic and proteolytic enzymes. The hydrolytic action of the enzymes converts triglycerides into free fatty acids that stimulate inflammation and edema and result in breakdown of the follicle wall. Chemotactic substances also may be released that involve mediation of inflammation by attraction of polymorphonuclear leukocytes.[2]

Treatment of acne should address the causative factors and be individualized according to severity. The combination of a topical retinoid, benzoyl peroxide, and antimicrobial agents is preferred. Retinoids are anticomedogenic and comedolytic and have some anti-inflammatory effects. Benzoyl peroxide is antimicrobial with some keratolytic effects. Topical antibiotics (e.g., erythromycin and clindamycin) have anti-inflammatory and antimicrobial effects. Combined oral contraceptives may be effective for acne in women.[3] Use of systemic therapies, including oral antibiotics, corticosteroids, and isotretinoin, is encouraged in more severe cases but may be limited by side effects. Dietary based guidelines need further investigation.[4] Acne surgery, including comedo extraction, intralesional steroids, and cryosurgery, may be useful in selected individuals. Severe scarring may be treated with dermabrasion, lasers, and resurfacing techniques. Special consideration must be given to treatment for those with darker skin because they have greater risk for hyperpigmentation and keloidal scarring.[5] Psychosocial morbidity is significant, particularly in adolescents.[5-7]

Acne conglobata is a highly inflammatory form of severe acne with communicating cysts and abscesses beneath the skin that can cause scarring. Remissions tend to occur during the summer, perhaps from more exposure to sunlight. This type of acne requires the use of systemic and combination therapies to prevent drug resistance.

DERMATITIS

Atopic Dermatitis

Atopic dermatitis (AD), also known as atopic eczema, occurs with a prevalence rate up to 20% in children. AD is increasing throughout the world.[8] Onset is usually from 2 to 6 months of age, and 85% of cases occur within the first 5 years of life; 75% to 80% of individuals with AD have a personal or family history of asthma, allergic rhinitis (hay fever), or food allergy. The cause of this chronic relapsing form of pruritic eczema involves an interplay of genetic predisposition, altered skin barrier function associated with filaggrin gene missense mutations (proteins that bind keratin in the epidermis), reduced ceramide (a stratum corneum lipid) levels, altered innate immunity, and altered immune responses to allergens, irritants, and microbes.[9]

There is debate as to whether the pathophysiology favors an "inside-out" explanation with immunologic dysregulation leading to epidermal barrier abnormality or an "outside-in" explanation with primary barrier dysfunction as the cause of the immunologic perturbations.[10] Regardless of the debate, both are involved in the disease. Positive skin tests to a variety of common food and inhalant allergens are seen in approximately 80% of individuals. Children with atopic dermatitis are more likely to have asthma.[11]

In AD, memory T cells in the blood express cutaneous lymphocyte antigen (CLA), which leads to the homing of lymphocytes to the skin. Inflammation is associated with activation of Th2 and Th1 cells with release of numerous cytokines, chemokines, interferon-gamma (IFN-γ), and granulocyte-macrophage colony-stimulating factor (GM-CSF). Activation of mast cells, eosinophils, and macrophages and expression of IgE contribute to the inflammation.[12]

Alterations in filaggrin protein lead to a defect of the epidermal barrier that causes transepidermal water loss and allows easy penetration of pathogens and allergens through the skin and a systemic hyperactive immune response. Filaggrin gene mutations also are associated with increased risk for asthma in AD and ichthyosis vulgaris (dry, scaly skin). In AD keratinocytes are deficient in their ability to express Toll-like antimicrobial peptides (see Chapter 7), and may predispose such individuals to skin colonization and infection with *Staphylococcus aureus,* viruses, and fungi.[13]

AD has a long-term course with frequent exacerbations, severe pruritus, and characteristic eczematoid appearance with redness, edema, and scaling (Figure 47-2). The skin becomes increasingly dry, sensitive, itchy, and easily irritated because the barrier function is impaired. Microscopic epidermal cracks that allow water to be expelled and irritants, allergens, and microbes

to enter further inflammation, drying, and cracking. Itching is the hallmark of atopic dermatitis, and rubbing and scratching to relieve the itch are responsible for many of the clinical skin changes of AD. Histamine level is elevated in AD lesions but is not considered a major pruritogen because blockage of H1 and H2 receptors alone is ineffective at relieving itch. However, H4 receptor blockers are being evaluated.[14] Pruritus is a complex process with immune and neurologic pathways.[15,16]

In infants, the rash appears primarily on the face, scalp, trunk, and extensor surfaces of the arms and legs. In older children and adults, the rash tends to be found on the neck, antecubital and popliteal fossae, and hands and feet. Lichenification (thickening of the epidermis from constant scratching) is more common in adults with chronic eczema. Individuals with AD tend to develop viral, bacterial, and fungal skin infections in the areas with eczema. The irritation and itching interfere with sleep and cause irritability.

There are no specific laboratory features of AD that can be used for diagnostic purposes, and diagnosis is based on clinical history and presentation of symptoms. Management of AD requires a systematic, multidimensional, individualized approach that considers the individual's skin reaction pattern and acuity of the rash.[17] Treatment guidelines establish the foundation of AD management, addressing the skin barrier defect with regular use of emollients and skin hydration along with the identification and avoidance of specific and nonspecific trigger factors. Various topical agents are mainstays of treatment. Topical corticosteroids and calcineurin inhibitors continue to dominate therapy and, to date, their safety record seems good (despite the Black Box warning issued in the United States). In severe cases that cannot be controlled, guidelines suggest systemic treatment options including systemic corticosteroids, cyclosporine A, ultraviolet light therapy, and wet wrap therapy being added to the topical treatment regimen. Systemic corticosteroids are known to be effective in short-term treatment of AD, but evidence is limited to support their use because of long-term side effects and rebound flaring.[18-20] Research is in progress to develop targeted molecular therapy that is safe and cost-effective.

Diaper Dermatitis

Diaper dermatitis is a form of irritant contact dermatitis initiated by a combination of factors that include prolonged exposure to and irritation by urine and feces, maceration by wet diapers, complications from use of airtight plastic diaper covers, and possibly increased association with intercurrent illnesses and early introduction of cereals. Disposable diaper designs have decreased diaper dermatitis in infants.[21] Diaper dermatitis is frequently secondarily infected with *Candida albicans.*

The lesions vary from mild erythema to erythematous papular lesions. Candidal (monilial) diaper dermatitis is usually very erythematous, with sharp margination and pustulovesicular satellite lesions (Figure 47-3).

Treatment includes changing the diaper frequently to keep the area clean and dry or frequently exposing the perineal area to air, using super-absorbent diapers, and applying topical protection with a product containing petrolatum or zinc oxide, or both. Topical antifungal medication is used to treat *C. albicans* when present.[22]

FIGURE 47-4 Impetigo. Multiple crusted and oozing lesions of impetigo. (From Kliegman RM et al: *Nelson textbook of pediatrics,* ed 19, Philadelphia, 2011, Saunders.)

INFECTIONS OF THE SKIN

Infectious diseases caused by bacteria, viruses, and fungi constitute the major forms of skin disease. Breaks in the skin integrity, particularly those that inoculate pathogens into the dermis and epidermis, may cause or exacerbate infections. Most infections tend to occur superficially; however, systemic signs and symptoms do develop occasionally and can be life threatening in immunosuppressed children.

Bacterial Infections

Impetigo Contagiosum

Impetigo is a common bacterial skin infection in infants and children. The mode of transmission is by both direct and indirect contact. The disease is more common in midsummer to late summer, with a higher incidence in hot, humid climates. Impetigo is particularly infectious among people living in crowded conditions with poor sanitary facilities or in settings such as daycare facilities. It affects children in good health, but conditions such as anemia and malnutrition are predisposing factors. There are two common types of impetigo: nonbullous and bullous. Both start as vesicles with a very thin vesicular roof composed of stratum corneum.

Nonbullous impetigo is a contagious, acute, superficial, vesiculopustular form of impetigo caused by *Staphylococcus aureus* or group A *Streptococcus pyogenes* (alone or in combination with *S. aureus*). The microorganisms are disseminated by direct physical contact from other infected individuals or through insect bites. The lesions begin as small vesicles with a honey-colored serum. Yellow to white-brown crusts form as the vesicles rupture (Figure 47-4). The lesions must be differentiated from herpes simplex lesions (see Figure 46-17, p. 1636). Untreated lesions may last for weeks and extend to cover a large area. In contrast to bullous impetigo, regional lymphadenitis is common.

Bullous impetigo is a rarer variant of impetigo caused by *S. aureus.*[23] The pathogen is often carried in the anterior nares, perineal region, or fingernails and is transmitted by contact with the individual or contaminated equipment.[24] The staphylococci produce bacterial toxins called *exfoliative toxins (ETs)* that cause a disruption in desmosomal adhesion molecules with blister formation.[25] The blisters enlarge or coalesce to form superficial bullae. There may be a few localized lesions or many lesions scattered over the skin. As the bullae rupture, a thin, flat, honey-colored crust appears.

The crust is the hallmark of impetigo. A moist, inflamed serum-weeping base is revealed when the crust is removed. The lesions are often located on the face around the nose and mouth, but the hands and other exposed areas are also involved. Regional lymphadenitis is uncommon. Treatment of choice for both types of impetigo is topical mupirocin and topical fusidic acid or oral antibiotics. Antibiotic therapy should be determined by bacterial culture and drug sensitivity because the prevalence of community-acquired methicillin-resistant *S. aureus*–associated impetigo is increasing. For extensive or complicated impetigo, systemic antibiotics may be warranted but beta-lactam antibiotics should be avoided if methicillin-resistant *S. aureus* (MRSA) is suspected.[23,26] Prompt treatment avoids complications, such as glomerulonephritis, necrotizing fasciitis, and septic shock syndrome. Handwashing and isolation of the infected child's washcloth, towels, drinking glass, and linen are important practices to control this highly contagious disease.

Staphylococcal Scalded-Skin Syndrome

Staphylococcal scalded-skin syndrome (SSSS) is the most serious staphylococcal infection that affects the skin and usually is seen in infants and children younger than 5 years.[27] SSSS is caused by virulent group II staphylococci, which produce an exfoliative toxin that attacks desmoglein and adhesion molecules and causes a separation of the skin just below the granular layer of the epidermis.[28] The toxins are usually produced at body sites other than the skin and arrive at the epidermis through the circulatory system. Staphylococci typically are not found in the skin lesions themselves. Adults have circulating antistaphylococcal antibodies and are better able to metabolize and excrete the toxin. Newborns and premature infants are at the highest risk because of immature immunity (absence of prior exposure to the toxin).

The clinical symptoms begin with fever, malaise, rhinorrhea, and irritability followed by generalized erythema with exquisite tenderness of the skin. There may be an associated impetigo, but the infection often begins in the throat or chest. The erythema spreads from the face and trunk to cover the entire body except the palms, soles, and mucous membranes. Within 48 hours, blisters and bullae may develop, giving the child the appearance of being scalded (Figure 47-5). The pain is severe. Fluid loss from ruptured blisters and water evaporation from denuded areas may cause dehydration and loss of body heat. Perioral and nasolabial crusting and fissures develop. In severe cases the skin of the entire body may slough. When secondary infection can be prevented, healing of the involved skin occurs in 10 to 14 days, usually without scarring.

Before medical intervention is begun, culture, histology, or exfoliative cytology must be done to differentiate SSSS from toxic epidermal necrolysis (TEN) (see p. 1664). When the infection is confirmed, treatment with oral or intravenous antibiotics is begun. Topical antibiotics are ineffective. The skin should be treated the same as that with a severe burn—with meticulous aseptic technique. Skin substitutes may be used for adjuvant

FIGURE 47-5 Staphylococcal Scalded-Skin Syndrome (SSSS). The skin lesions, showing desquamation and wrinkling of the skin margins, appeared 1 day after drainage of a staphylococcal abscess. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy*, ed 5, St Louis, 2010, Mosby.)

therapy.[29] Special care is required in serious cases and when the lips and eyelids are involved.[27]

Fungal Infections

Fungal disorders are known as *mycoses* and, when caused by dermatophytes (fungi that thrive on keratin), the mycoses are termed *tinea* (dermatophytosis or ringworm). The different types of tinea are classified according to their location on the body. **Tinea pedis** (a chronic, superficial fungal infection of the skin of the foot) occurs in children but is rare. Scaling disorders of the toes and feet in prepubertal children are usually eczema. Tinea capitis (infection of the scalp) and tinea corporis (infection of the body) are much more common in children than in adults. Dermatophytes of the genus *Epidermophyton* are the major cause of superficial fungal infections in children.[30] These dermatophytes invade the stratum corneum and not the remainder of the epidermis or dermis. The inflammatory response is thought, in part, to be secondary to the toxins released by the dermatophyte. It is important to confirm by culture the exact microorganism that is causing the fungal infection before commencing therapy.

FIGURE 47-6 Tinea Capitis. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Tinea Capitis

Tinea capitis, a fungal infection of the scalp, is the most common fungal infection of childhood. It rarely affects infants and is seen in children younger than age 12. Primary microorganisms responsible for the disease are *Trichophyton tonsurans and Microsporum canis. T. tonsurans* is transmitted by human-to-human contact. Areas of crowding are the most prevalent environments for this microorganism, which frequently affects inner-city children. *T. tonsurans* is often the predominant dermatophyte found in North America; many of these infections are not symptomatic.[31] The prevalence of asymptomatic carriers among household contacts of a child with active *T. tonsurans* disease is high. *M. canis* is found on cats, dogs, and certain rodents. Humans appear to be a terminal host for *M. canis,* and children who handle such animals are possible hosts. Human-to-human transmission does not occur with *M. canis.*

When symptoms are present, the clinical presentations vary, depending on the microorganism. Often the lesions are circular and manifest by broken hairs 1 to 3 mm above the scalp, leaving a partial alopecia 1 to 5 cm in diameter[32] (Figure 47-6). Slight erythema and scaling with raised borders can be observed.

Diagnosis is best confirmed by performing Wood light examination, potassium hydroxide (KOH) examination, and fungal culture, in that order. *T. tonsurans* does not fluoresce with Wood light examination. Oral griseofulvin is the treatment of choice because topical fungicides do not penetrate to the hair bulb. Terbinafine, itraconazole, and fluconazole are effective alternatives.[31] Adjunct therapy includes 2% ketoconazole and 1% selenium sulfide shampoos. Treatment of household contacts with a sporicidal shampoo should be considered and co-sleeping and comb-sharing must be discouraged.

Tinea Corporis

Tinea corporis (ringworm) is a common superficial dermatophyte infection in children. The microorganisms most commonly responsible for this disease are *M. canis* and *Trichophyton mentagrophytes.* As in tinea capitis, contact with kittens and puppies is a common source of the disorder. Tinea corporis preferentially affects the nonhairy parts of the face, trunk, and limbs. Lesions are often erythematous, round or oval scaling patches that spread peripherally with clearing in the center,

creating the ring appearance, which is why this disease is commonly referred to as *ringworm*. The lesions are distributed asymmetrically, and multiple lesions (when present) overlap. Transmission occurs by direct contact with an infected lesion and through indirect contact with personal items used by the infected person. Potassium hydroxide examination of the scale from the border of the lesions confirms the diagnosis for most lesions. Most lesions respond well to applications of appropriate topical antifungal medications.[30]

Thrush

Thrush is the term used to describe the presence of *Candida albicans* in the mucous membranes of the mouth of infants and less commonly in adults, and both may be immune compromised. *C. albicans* penetrates the epidermal barrier more easily than other microorganisms because of its keratolytic proteases and other enzymes. *C. albicans* attracts neutrophils to skin sites of invasion but evades neutrophil killing.[33] Thrush is characterized by the formation of white plaques or spots in the mouth that lead to shallow ulcers. The tongue may have a dense, white covering. The underlying mucous membrane is red and tender and may bleed when the plaques are removed. The disease is often accompanied by fever and gastrointestinal irritation. The infection commonly spreads to the groin, buttocks, and other parts of the body. Treatment may be difficult and may include oral antifungal washes, such as nystatin oral suspension. Gentian violet can also be effective but is messy.[34] Simultaneous treatment of a *Candida* nipple infection or vaginitis in the mother is helpful in reducing the *C. albicans* surface colonization of the infant. Feeding bottles and nipples should be sterilized to prevent reinfection. The diaper area should be kept clean and dry.

Viral Infections

Viral infections of the skin in children are caused by poxvirus, papovavirus, and herpesvirus. The most common infections are described here.

Molluscum Contagiosum

Molluscum contagiosum is a common highly contagious poxvirus infection of the skin and occasionally conjunctiva that affects school-aged children and sexually active young adults. The disease can be more severe or prolonged in individuals with atopic dermatitis and a variety of immunodeficient states, including acquired immunodeficiency syndrome (AIDS). It is transmitted by skin-to-skin contact (e.g., contact sports), autoinoculation, and fomites, such as clothing, wash devices, and towels. The poxvirus induces epidermal cell proliferation and blocks immune responses that would control the virus. The epidermis grows down into the dermis to form saccules containing clusters of virus. The characteristic molluscum body is composed of mature, immature, and incomplete viruses and cellular debris.[35]

The lesions of molluscum are discrete, slightly umbilicated, dome-shaped papules 1 to 5 mm in diameter that appear anywhere on the skin or conjunctiva. The skin distribution in children is mainly on the trunk, face, and extremities (Figure 47-7). The pubic, genital, and perineal areas are favored in adults. Usually no inflammation surrounds molluscum lesions unless they are traumatized or secondary infection occurs. Scarring may occur with healing.

The best three diagnostic procedures are: (1) staining smears of the expressed molluscum body, (2) examining a biopsy, and (3) inoculating a molluscum suspension into cell cultures to demonstrate the cytotoxic reactions. Most lesions are self-limiting and clear in 6 to 9 months if not manipulated. However, because children often do manipulate these lesions, spontaneous involution may take 2 to 4 years without therapy.

Treatment options include immunomodulatory and antiviral therapy and destructive procedures (cryotherapy, curettage, or laser ablation); however, no treatment is universally effective. Treatment is recommended for genital molluscum to prevent sexual transmission and autoinoculation.[36] Destructive therapy is poorly tolerated by children. Measures to prevent spread of infection must be taken and recurrences are common.

Rubella (German or 3-Day Measles)

Rubella is a common communicable disease of children and young adults caused by a ribonucleic acid (RNA) virus that enters the bloodstream through the respiratory route. This disease is mild in most children. The incubation period ranges from 14 to 21 days. Prodromal symptoms are few but may include enlarged cervical and postauricular lymph nodes, low-grade fever, headache, sore throat, runny nose, and cough. A faint-pink to red, coalescing maculopapular rash develops on the face, with spread to the trunk and extremities, sparing the palms of the hands and soles of the feet, 1 to 4 days after the onset of initial symptoms (Figure 47-8). The rash is thought to be the result of virus dissemination to the skin. The rash subsides after 2 to 3 days, usually without complications. Children are generally not contagious after development of the rash. There is lifelong immunity to rubella—as there is for measles, chickenpox, and roseola—after contracting the disease. Differential presentations of viral diseases producing rashes are given in Table 47-1.

FIGURE 47-7 Molluscum Contagiosum. Waxy pink globules with umbilicated centers. (From Habif TP: *Clinical dermatology: a color guide to diagnosis and therapy,* ed 5, St Louis, 2010, Mosby.)

Vaccination for rubella is usually combined with vaccines for mumps and measles (rubeola) (MMR). Vaccine recommendations are presented in Chapter 10. Measles are known to occur in previously immunized children.[37] Rubella has almost been eliminated in the United States because of vaccination campaigns. However, challenges to maintain elimination include large outbreaks of measles in highly traveled developed countries, frequent international travel, and clusters of U.S. residents who remain unvaccinated because of personal belief exemptions.[38]

FIGURE 47-8 Rubella (Measles). Maculopapular rash with tendency to coalesce. The rash is similar to rubeola (red measles) but less intense. (From Marx JA et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, Philadelphia, 2010, Mosby.)

Although the MMR vaccine may rarely be associated with adverse neurologic events (e.g., seizures because of fever, deafness), studies conclude that MMR immunization does not cause autism.[39,40] Lack of vaccination, however, leads to significant morbidity and mortality, with pneumonia, croup, and encephalitis being causes of death worldwide.[41,42]

Women of childbearing age are immunized if their rubella hemagglutination-inhibition titer is low. Pregnancy should be avoided for 3 months after vaccination because the attenuated virus in the vaccine may remain for this period. However, accidental receipt of MMR vaccination is not known to cause maternal or fetal complications, or both.[43] Pregnant women who have rubella early in the first trimester may have a fetal death or a fetus that develops congenital defects.[44]

There is no specific treatment for rubella. Recovery is spontaneous, although lymph nodes may remain enlarged for weeks. Supportive therapy includes rest, fluids, and use of a vaporizer. In rare cases a mild encephalitis or peripheral neuritis may follow rubella.

Rubeola (Red Measles)

Rubeola is a highly contagious, acute viral disease of children. It is transmitted by direct contact with droplets from infected persons and is caused by an RNA-containing paramyxovirus with an incubation period of 7 to 12 days, during which time no symptoms manifest. The virus enters the respiratory tract and attaches to dendritic cells and alveolar macrophages, amplifies in local lymphatic tissue, and progresses to systemic disease.[45] Prodromal symptoms include high fever (up to 40.5° C [104.9° F]), malaise, enlarged lymph nodes, runny nose, conjunctivitis, and "barking" cough. Within 3 to 4 days, an erythematous maculopapular rash develops over the head and spreads distally over the trunk, extremities, hands, and feet. Early lesions blanch with pressure, followed by a brownish hue that does not blanch as the rash fades. Characteristic pinpoint white spots surrounded by an erythematous ring develop over the buccal mucosa and are known as *Koplik spots.* These spots precede the

TABLE 47-1 DIFFERENTIAL PRESENTATION OF VIRAL DISEASES PRODUCING RASHES

VIRAL DISEASE	INCUBATION	PRODROMAL SYMPTOMS	DURATION/ CHARACTERISTICS	CLINICAL SYMPTOMS
Rubella (German measles)	14-21 days	1-2 days Mild fever Malaise Respiratory symptoms	1-3 days Pink-red maculopapular rash Face and trunk	Enlarged and tender occipital and periauricular nodes
Rubeola (measles)	7-12 days	2-5 days Fever Cough Respiratory symptoms	3-5 days Purple-red to brown maculopapular papules Face, trunk, extremities	Koplik spots 1-3 days before rash Rash develops when fever subsides
Roseola (exanthema subitum)	5-15 days	2-5 days High fever	1-3 days Red macular papules Neck and trunk	
Varicella (chickenpox)	11-20 days	1-2 days Low-grade fever Cough May be asymptomatic	Red papules, vesicles, pustules in clusters	Eruption of new lesions for 4-5 days Occasional ulcerative lesion in the mouth

rash by 1 to 2 days and are usually missed because they appear so early. The rash then subsides within 3 to 5 days.

Complications associated with measles may be caused by the primary infection or a secondary bacterial infection. Measles encephalitis occurs in about 1 of 800 cases, and most children recover completely. Only a small minority develop permanent brain damage or die. Bacterial complications include otitis media and pneumonia, usually caused by group A hemolytic streptococcus, *Haemophilus influenzae,* or *S. aureus* infection.

Measles is prevented by a single vaccination of live attenuated measles virus. There is no specific treatment for measles, and supportive therapy is the same as for rubella. Antibiotic therapy is initiated if secondary bacterial infections develop.

Roseola (Exanthema Subitum)

Roseola is a presumed viral infection of infants between 6 months and 2 years of age, but it can be seen in children as old as 4 years. The incubation period is 5 to 15 days, followed by the sudden onset of fever (38.9° to 40.5° C [102° to 104.5° F]) that lasts 3 to 5 days. After the fever an erythematous, nonpruritic macular rash that lasts about 24 to 48 hours develops primarily over the trunk, neck, and arms. Children usually feel well, eat normally, and have few other symptoms. Usually no treatment is required and there are no complications.

Chickenpox and Herpes Zoster

Chickenpox (varicella) and herpes zoster (shingles) are produced by the varicella-zoster virus (VZV). VZV is a complex herpes group deoxyribonucleic acid (DNA) virus. The incubation period is 10 to 27 days, averaging 14 days. Productive infection occurs within keratinocytes such that the vesicular lesions occur in the epidermis, and an inflammatory infiltrate is often present. Histologically, VZV lesions form intraepidermal vesicles. Infected keratinocytes degenerate, swell, detach from each other, and often contain inclusions surrounded by a clear halo and a circle of darkly staining chromatin. As the vesicle evolves, polymorphonuclear cells enter the vesicle and can lead to a pustular appearance. The vesicle eventually ruptures and is followed by crust formation. On mucous membranes the vesicles rupture and leave superficial, transient ulcers. Varicella occurs in people not previously exposed to VZV, whereas herpes zoster occurs in partially immune individuals who have had varicella.[46]

Chickenpox (Varicella). **Chickenpox** is a disease of early childhood, with 90% of children contracting the disease during the first decade of life. It is a highly contagious virus that is spread by person-to-person contact and airborne droplets. Introduction of an infected person into a household results in a 90% possibility of susceptible persons in the household developing the disease within the incubation period—usually 14 days. Children are contagious for at least 1 day before development of the rash. Transmission of the virus may occur until approximately 5 to 6 days after the onset of the first skin lesions in healthy children. In immunocompromised children the virus is recoverable for a longer period, but these children must be considered contagious for at least 7 to 10 days. Healthy children who develop chickenpox have no prodromal symptoms. The first sign of illness may be itching or the appearance of vesicles, usually on the trunk, scalp, or face. The rash later spreads to the extremities. Characteristically, lesions can be seen in various stages of maturation with macules, papules, and vesicles present in a particular area at the same time (Figure 47-9). The vesicular lesions are superficial and can be easily ruptured. New lesions will erupt for 4 to 5 days, until there are approximately 100 to 300 in different stages of development. The vesicles become crusted, with only the crust remaining. Occasionally a vesicle may appear on the palm later in the disease. Although uncommon, ulcerative lesions are sometimes seen in the mouth and, less commonly, on the conjunctiva and pharynx. Fever usually lasts 2 to 3 days and ranges from 38.5° to 40° C [101.3° to 104° F]).

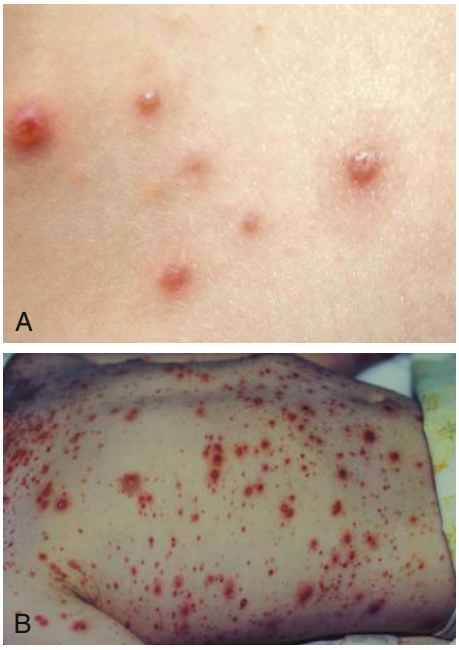

FIGURE 47-9 Chickenpox. **A,** Early stage lesions; **B,** late stage lesions. (**A** from Long SS et al: *Principles and practice of pediatric infectious diseases,* ed 4, Philadelphia, 2012, Saunders. **B** courtesy of David Effron, MD. From Marx J et al: *Rosen's emergency medicine: concepts and clinical practice,* ed 7, Philadelphia, 2010, Mosby.)

Complications are rare in children but more common in adults. They can include transient hematuria (from rupture of vesicles in the bladder), epistaxis, laryngeal edema, and varicella pneumonia. One case of chickenpox produces almost complete immunity against a second attack. Rarely, the fetus may be malformed (congenital varicella syndrome) if chickenpox develops in the mother in the first trimester of pregnancy.[47]

Infants whose mothers have chickenpox at any stage of pregnancy have a higher risk of developing herpes zoster during the first few years of life. Administration of maternal varicella-zoster immunoglobulin before rash development, with or without antiviral medication, can modify the progression of the disease.[48]

Uncomplicated chickenpox requires no specific therapy. Baths, wet dressings, and oral antihistamines are occasionally helpful to relieve itching and to prevent secondary infection as a result of scratching. Oral antistaphylococcal drugs should be given if secondary bacterial infection is present. Zoster immune globulin may be administered to immunodeficient individuals

if given within 72 hours after exposure to chickenpox. Oral antiviral drugs may be valuable in reducing symptoms in otherwise healthy children as well as in immunosuppressed or other select groups of children.[49] Chickenpox can be prevented with a safe and effective vaccine (see Chapter 10).

Herpes Zoster. Although herpes zoster (shingles) occurs mainly in adults, approximately 5% of cases are in children younger than 15 years.[50] The pathophysiology and treatment are reviewed in Chapter 46.

Smallpox

Smallpox (variola) is a highly contagious and deadly but preventable disease. It is caused by poxvirus variolae. Because of worldwide mass immunization, the world is now virtually free of smallpox. Concerns regarding smallpox as a weapon of bioterrorism have led to vaccination programs for the military and for selected civilian populations. The U.S. government has an adequate supply of smallpox vaccine to vaccinate the population in the event of an emergency.[51]

INSECT BITES AND PARASITES

Insect bites and infestations are common causes of skin disorders in children and adults. Skin damage occurs by various mechanisms, including trauma of bites and stings, allergic reactions, transmission of disease, injection of substances that cause local or systemic reactions, and inflammatory reactions from retained mouthparts.

Scabies

Scabies is a contagious disease caused by the itch mite, *Sarcoptes scabiei* (Figure 47-10, *A*), that can colonize the human epidermis. Scabies is a common skin infection in tropical settings and affects large numbers of people, particularly children. It is transmitted by personal contact and by infected clothing and bedding. Scabies is often epidemic in areas of overcrowded housing, in areas with poor sanitation, or in long-term care institutions. Scabies is often associated with immunocompromised individuals, such as those with human T-cell leukemia/lymphoma virus I (HTLV-1) and human immunodeficiency virus (HIV), and can facilitate *Streptococcus pyogenes* and *Staphylococcus aureus* skin infection.[52] Infestation is initiated by a female mite that tunnels into the stratum corneum, depositing eggs and creating a burrow several millimeters to 1 cm long. Over a 3-week period, the eggs mature into adult mites, which sometimes can be recognized as tiny dots at the end of intact burrows.

Symptoms appear 3 to 5 weeks after infestation. The primary lesions are burrows, papules, and vesicular lesions, with severe itching that worsens at night. Two or three bites (commonly referred to as "breakfast, lunch, and dinner") usually appear in a line on exposed areas of the skin. Itching is thought to be related to sensitization to the larval stages of the parasite. In older children and adults the lesions occur in the webs of fingers, axillae, and creases of the arms and wrists; along the belt line; and around the nipples, genitalia, and lower buttocks. Infants and young children have a different pattern of distribution, with involvement of the palms, soles, head, back, neck, and face (see Figure 47-10, *B*). Secondary infections and crusting develop from scratching and eczematous changes.

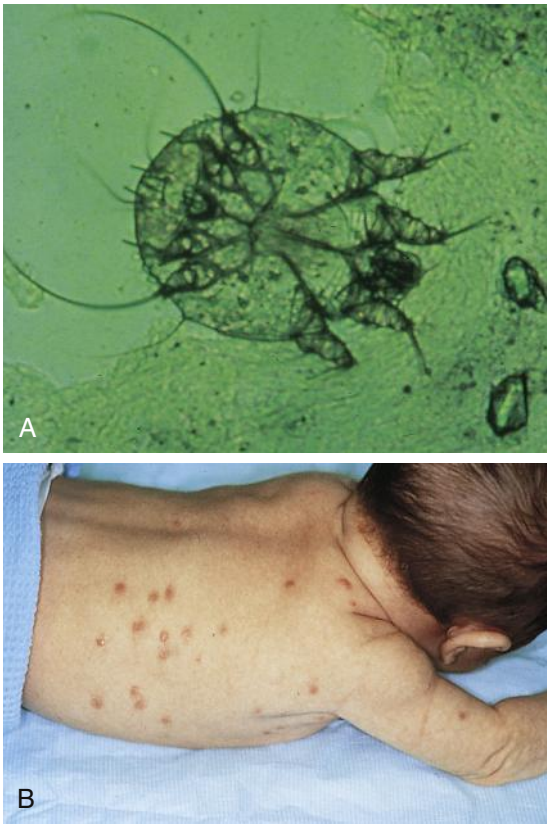

FIGURE 47-10 Scabies. **A,** Scabies mite, as seen clinically when removed from its burrow. **B,** Characteristic scabies bites. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Diagnosis of scabies is made by observation of the tunnels and burrows and by scraping of the skin with microscopic examination of the mite or its eggs or feces. Treatment is the application of permethrin cream, a scabicide. Generalized scabies is treated with oral ivermectin.[53] Even with elimination of all viable scabies microorganisms, itching may persist for 10 days or longer. All clothing and linens should be washed and dried in hot cycles or dry-cleaned.

Pediculosis (Lice Infestation)

The three known types of human lice are: (1) the head louse *(Pediculus capitis)*, (2) the body louse *(Pediculus corporis)*, and (3) the crab or pubic louse *(Phthirus pubis)*. They are highly contagious parasites that survive by sucking blood. The female louse reproduces every 2 weeks, producing hundreds of nits as newly hatched lice mate with old lice. The mouthparts are shaped for piercing and sucking and attach to the skin while feeding. When piercing the skin, the louse secretes a toxic saliva; the mechanical trauma and toxin produce a pruritic dermatitis. Head and body lice are acquired by personal contact, combs, or brushes. Crab lice are spread by body contact, such as contact with an infected adult. Sharing clothing is also a common source of transmission.[54]

FIGURE 47-11 Flea Bites. Flea bite producing an urticarial wheal with central puncture. (Courtesy Department of Pediatrics, Division of Allergy and Immunology, National Jewish Health.)

Itching is the major symptom of lice infestation. In head lice infestation the ova attach to hairs above the ears and in the occipital region. The primary lesion of the body louse is a pinpoint red macule, papule, or wheal with a hemorrhagic puncture site. The primary lesion often is not seen because it is masked by excoriations, wheals, and crusts. The crab louse is found on pubic hairs but also may involve other body hair such as eyelashes, mustache, beard, and axillae. Young children particularly may become infected with crab lice on their eyebrows or eyelashes.

The live louse, 2 to 3 mm long, is rarely observed, although the ova, or nits, can be observed as oval, yellowish pinpoint specks fastened to a hair shaft. The ova fluoresce under an ultraviolet light (Wood lamp) and can be best observed with a microscope. Infestations can be treated with a topical pediculicide (i.e., permethrin) or oral ivermectin.[55] Head lice are effectively treated with topical ivermectin.[56] All clothes, towels, bedding, combs, and brushes should be washed and dried in hot air or boiled, or the clothes should be ironed. Individuals who have personal contact also should be treated.

Fleas

Young children are very susceptible to **flea bites,** and the most common are the bites of cat, dog, and human fleas.[57] Bites occur in clusters along the arms and legs or where clothing fits tightly. The bite produces an urticarial wheal with a central hemorrhagic puncture (Figure 47-11). Treatment includes spraying carpets, crevices, and furniture with malathion or lindane powder. Infected animals should be treated, and clothes and bedding should be washed in hot water.

FIGURE 47-12 Bullous Bedbug Bites. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Bedbugs

The common bedbug, *Cimex lectularius,* is a blood-sucking nocturnal parasite of man. Chickens, bats, and some domestic animals are the other hosts for this bug.[58] **Bedbugs** live in the crevices and cracks of floors, walls, and furniture and in bedding or furniture stuffing. They are 3 to 5 mm long and reddish brown. Bedbugs are nocturnal, emerging to feed in darkness, are attracted by warmth and carbon dioxide, and attach to the skin to suck blood. Feeding occurs for 5 to 15 minutes; then the bedbug leaves. It will move long distances to search for food and can travel from house to house.

Immunologic reactions to bedbug saliva vary, but bites typically yield erythematous and pruritic papules. The face and distal extremities, areas uncovered by sleeping clothes or blankets, are preferentially involved. If the host has not been previously sensitized, the only symptom is a red macule that develops into a nodule, lasting up to 14 days. In sensitized children and adults, pruritic wheals, papules, and vesicles may form (Figure 47-12) and, rarely, anemia and angioedema. Most lesions respond to antihistamines or corticosteroids. Secondary infections require antibiotic treatment. Bedbugs are eliminated by inspecting and cleaning or disposing of bedding, mattresses, furniture, and other contaminated items, and by using applications of approved insecticides, usually by a professional.[59]

HEMANGIOMAS AND CUTANEOUS VASCULAR MALFORMATIONS

Cutaneous vascular anomalies are frequent tumors of early infancy and can be categorized as either hemangiomas or vascular malformations.

Hemangiomas

Hemangiomas are benign tumors that form from the rapid growth of vascular endothelial cells, which results in formation of extra blood vessels. Hemangiomas can be superficial or deep.[60] Superficial hemangiomas are known as strawberry hemangiomas, and deep lesions are known as cavernous hemangiomas. The etiology may be related to embolization of fetal placental endothelial cells in association with placental trauma or loss of placental angiogenic inhibitor of placental and maternal origin.[61] There is proliferation of mast cells that are thought

FIGURE 47-13 Strawberry Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

FIGURE 47-14 Cavernous Hemangioma. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

to promote the angiogenesis. Infiltration of fat cells, fibrosis, and the rich vascular network give the lesions a firm, rubbery feel. Females are affected more often than males. About 30% of hemangiomas are apparent at birth, with most emerging during the first few weeks of life; they grow rapidly during the first few years, and then shrink or involute during childhood years. With involution the lesions become darker in color and then gradually turn to a flesh color. There may be some residual telangiectasia. Most require no treatment depending on location. Hemangiomas located over the eye, ear, nose, mouth, urethra, or anus may require treatment because they interfere with function and have a higher risk for infection or injury. Rapidly progressing hemangiomas are treated with propranolol with regression occurring within 2 weeks; propranolol should be considered a first-line agent.[62] Other therapies include systemic or intralesional steroids, cryosurgery, laser surgery, sclerotherapy, and embolization. Interferons, vincristine, cyclophosphamide, and radiotherapy can suppress angiogenesis.

Strawberry hemangiomas are distinct superficial hemangiomas that may be present at birth but usually emerge 3 to 5 weeks after birth. They proliferate and become bright red and elevated with minute capillary projections that give them a strawberry appearance. Only one lesion is usually present, and it is located on the head and neck area or trunk (Figure 47-13). After the initial growth, the lesion grows at the same rate as the child and then starts to involute at 12 to 16 months of age. Approximately 90% of strawberry hemangiomas involute by 5 to 6 years of age, usually without scarring.

Cavernous (congenital) hemangiomas are present at birth and have larger and more mature vessels within the lesion than strawberry hemangiomas. Some lesions, however, are composed of a mixture of strawberry and cavernous hemangiomas. They appear primarily on the head and neck, are bluish red, and have less distinct borders (Figure 47-14). Cavernous hemangiomas grow rapidly up to 6 months of age and mature by 1 year of age. A period of involution begins and proceeds for 6 to 12 months, with complete involution by 2 to 3 years in 30% of children and by 9 years of age in 90% of children.

Vascular Malformations

Vascular malformations are congenital anomalies of blood vessels present at birth but may not be apparent for several years. They grow proportionately with the child and never regress.[63] The malformations occur equally among males and females. Occasionally they expand rapidly, particularly during the hormonal changes of puberty or pregnancy and in association with trauma. Vascular malformations are classified as low flow or high flow. *Low-flow malformations* involve capillaries, veins, and lymphatics. *High-flow malformations* involve arteries. In addition to locations within the skin they may involve the gastrointestinal tract, bone (Maffucci syndrome), facial capillary malformation, skin, vascular malformation of the eye, and vascular malformation of the brain (leptomeningeal hemangioma—Sturge-Weber syndrome).[64] *Overgrowth syndromes* can occur with either high- or low-flow malformations, with overgrowth of the underlying structures (i.e., legs, arms, facial bones). The most common vascular malformation is nevus flammeus (port-wine stain) and salmon patches (stork bite, angel kiss).

Port-wine (nevus flammeus) stains are congenital malformations of the dermal capillaries. **Sturge-Weber syndrome** is a port-wine stain distributed along the ophthalmic branch of the trigeminal nerve and is associated with the leptomeninges of the brain and choroid, glaucoma, seizures, stroke, and intellectual disability. These capillary malformation are associated with a mutation in the *GNAQ* gene (Guanine nucleotide-binding protein G, q polypeptide).[64a] The lesions are flat, and their color ranges from pink to dark reddish purple. They are present at birth or within a few days after birth and do not fade with age. Involvement of the face and other body surfaces is common, and the lesions may be large (Figure 47-15). During adolescence and later adult years, the port-wine stain may become papular and cavernous. The flashlamp pulsed dye laser

FIGURE 47-15 Capillary Malformation in a Child. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

is the treatment of choice to successfully lighten the color and flatten the more nodular and cavernous lesions.[64] Waterproof cosmetics may be used to cover the lesions.

Salmon patches (nevus simplex) are macular pink lesions present at birth and located on the nape of the neck, forehead, upper eyelids, or nasolabial fold. They are a more superficial variant of nevus flammeus and one of the most common congenital malformations in the skin. The pink color results from distended dermal capillaries, and 95% fade by 1 and 3 years of age. Those located at the nape of the neck may persist for a lifetime, but generally do not present a cosmetic problem.

OTHER SKIN DISORDERS

Miliaria

Miliaria is a dermatosis commonly seen in infants. It is characterized by a vesicular eruption after prolonged exposure to perspiration, with subsequent obstruction of the eccrine ducts. There are two forms of miliaria: miliaria crystallina and miliaria rubra. In **miliaria crystallina,** ductal rupture occurs within the stratum corneum and appears as 1- to 2-mm clear vesicles without erythema. They rupture within 24 to 48 hours and leave a white scale. In miliaria rubra the ductal rupture occurs in the lower epidermis, with inflammatory cells attracted to the site of the rupture. **Miliaria rubra (prickly heat)** is characterized by 2- to 4-mm discrete erythematous papules or papulovesicles (Figure 47-16). Both forms may become secondarily infected, requiring treatment with systemic antibiotics. The key to management is avoidance of excessive heat and humidity, which cause sweating. Light clothing, cool baths, and air conditioning assist in keeping the skin surface dry and cool.

FIGURE 47-16 Miliaria Rubra. Note discrete erythematous papules or papulovesicles. (Courtesy Department of Dermatology, School of Medicine, University of Utah.)

Erythema Toxicum Neonatorum

Erythema toxicum neonatorum (toxic erythema of the newborn) is a benign, erythematous accumulation of macules, papules, or pustules that appear at birth or 3 to 4 days after birth. The lesions first appear as a blotchy, macular erythematous rash. The macules vary from 1 mm to 1 cm. When papules or pustules develop, they are light yellow or white and 1 to 3 mm in diameter. There may be few or several hundred lesions and any surface of the body can be affected, with the exception of the palms and soles, where there are no pilosebaceous follicles. The cause of the lesion is unknown but it may be related to an innate immune response to the first commensal microflora with release of mast cell mediators. Eosinophils are abundant in the lesions.[65] It is self-limiting and resolves spontaneously within a few weeks of birth. No treatment is required.

Stevens-Johnson Syndrome and Toxic Epidermal Necrolysis

Stevens-Johnson syndrome (SJS) and **toxic epidermal necrolysis (TEN)** are rare, severe, immune drug reactions that are considered to be the same pathologic process but with TEN being more extensive. The mortality is between 5% and 35%. Hypersensitivity to drugs includes allopurinol, sulfonamides, nonsteroidal anti-inflammatory agents, anticonvulsants (i.e., phenytoin), and others. There is widespread epidermal (keratinocyte) apoptosis and detachment with drug-specific cytotoxic T cells and macrophages involved in the immunopathology.[66,67] Bursts of nitric oxide formation have been proposed as the cause of epidermal apoptosis and necrosis. There is destruction of the epidermis in toxic epidermal necrolysis.[68]

The onset of skin eruptions is preceded by malaise, anorexia, fever, and mild inflammation of the eyelids, conjunctiva, mouth, or genitalia. Erythema with tenderness is first described in the trunk, face, and palms, extending to the groin and mucous membranes. Blisters and bullae form and large areas of necrotic epidermis may be shed, leaving open, weeping, painful areas of underlying skin. Complications can include dehydration, protein loss, altered temperature regulation, ocular complications leading to blindness, and organ failure. About one third of children have pulmonary complications.[69] A severity of illness score for toxic epidermal necrolysis (SCORTEN)

syndrome guides treatment and predicts mortality.[70] TEN must be confirmed by skin biopsy to differentiate from staphylococcal scalded-skin syndrome (SSSS) and acute graft-versus-host disease. Skin biopsy shows full-thickness epidermal necrosis and subepidermal blister formation. Treatment requires prompt withdrawal of causative drugs and intensive burn equivalent management, preferably in a burn unit. Treatment with corticosteroids and intravenous immunoglobulin is controversial and needs further study, which is difficult because the disease is so rare.[71,72]

SUMMARY REVIEW

Acne Vulgaris

1. Acne vulgaris is the most common skin disease, affecting 85% of the population between the ages of 12 and 25 years.
2. Acne is characterized by noninflammatory and inflammatory lesions related to follicular hyperkeratinization, excessive sebum production, plugging of sebaceous glands, and *P. acnes* colonization. Acne conglobata is a severe form of acne with communicating cysts and abcesses.

Dermatitis

1. Atopic dermatitis is associated with elevated IgE levels, a family history of asthma and hay fever, and altered skin barrier function. Red, scaly lesions commonly occur on the face, cheeks, and flexor surfaces of the extremities in infants and young children.
2. Diaper dermatitis is a type of irritant contact dermatitis initiated by a combination of factors that include prolonged exposure to urine and feces; frequently the infant becomes infected secondarily with *C. albicans*.

Infections of the Skin

1. Impetigo is a contagious bacterial disease that occurs in two forms: bullous and vesicular (contagious). The toxins from the bacteria produce a weeping lesion with a honey-colored crust.
2. SSSS is a staphylococcal skin infection that occurs more commonly in young children with low titers of antistaphylococcal antibody. Painful blisters and bullae form over large areas of the skin, requiring systemic antibiotics for treatment.
3. Tinea capitis (infection of the scalp) and tinea corporis (infection of the body) are fungal infections caused by dermatophytes.
4. *C. albicans* infection is a superficial fungal infection of the mouth (thrush).
5. Molluscum contagiosum is a poxvirus of the skin that produces pale papular lesions filled with viral and cellular debris.
6. Rubella (also known as *German* or *3-day measles*) is a communicable disease characterized by fever, sore throat, enlarged cervical and postauricular nodes, and a generalized maculopapular rash that lasts 1 to 4 days.
7. Rubeola is a highly contagious disease of children. Symptoms include high fever, enlarged lymph nodes, conjunctivitis, and a red rash that begins on the head and spreads to the trunk and extremities and lasts 3 to 5 days. Bacterial and viral complications may accompany rubeola.
8. Roseola is a benign disease of infants with a sudden onset of fever that lasts 3 to 5 days, followed by a rash that lasts 24 hours.
9. Chickenpox (varicella) is a highly contagious disease caused by the VZV. Vesicular lesions occur on the skin and mucous membranes. Individuals are contagious from 1 day before the development of the rash until about 6 days after the rash develops.
10. Herpes zoster (shingles) is a viral eruption of vesicles on the skin along the distribution of a sensory nerve caused by latent activation of the VZV. Children with immune suppression develop more serious complications.
11. Smallpox (variola) is a highly contagious, deadly disease that has been eradicated worldwide by vaccination.

Insect Bites and Parasites

1. Scabies is an itching lesion caused by the itch mite that burrows into the skin, forming papules and vesicles. The mite is very contagious and is transmitted by direct contact.
2. Pediculosis (lice infestation) is caused by blood-sucking parasites that secrete a toxic saliva and damage the skin to produce a pruritic dermatitis. Lice are spread by direct contact and are recognized by the ova, or nits, that attach to the shaft of body hairs.
3. Flea bites produce a pruritic wheal with a central puncture site and occur as clusters in areas of tight-fitting clothing.
4. Bedbugs are blood-sucking parasites that live in cracks of floors, furniture, or bedding and feed at night. They produce pruritic wheals and nodules.

Hemangiomas and Vascular Malformations

1. Hemangiomas are benign vascular tumors that emerge at birth and resolve spontaneously through the childhood years. Strawberry hemangiomas (distinct, raised vascular lesions) are more superficial, and cavernous hemangiomas, with larger and more mature vessels, are deeper lesions.
2. Vascular malformations are congenital anomalies of blood vessels. Low-flow malformations involve capillaries, veins, and lymphatics; high-flow malformations involve arteries.
3. Nevus flammeus (port-wine stain) is a deeper congenital malformation of the dermal capillaries, and salmon patches are more superficial vascular malformations.

Other Skin Disorders

1. Miliaria is characterized by small pruritic papules or vesicles that result from prolonged exposure to perspiration and subsequent obstruction of the eccrine ducts in infants.
2. Erythema toxicum neonatorum is a benign, erythematous, accumulation of macules, papules, and pustules that appear at birth or 3 to 4 days after birth and then spontaneously resolve within a few weeks.
3. SJS and TEN (the severe form of SJS) are severe immune blistering skin reactions to drugs.

CHAPTER OUTLINE

Shock, 1668
Cellular Alterations and Impairment of Cellular Metabolism, 1669
Types of Shock, Clinical Manifestations, and Treatment, 1671
Multiple Organ Dysfunction Syndrome, 1679
Burns, 1685
Epidemiology and Etiology, 1685
Burn Wound Depth, 1685

Shock occurs when the cardiovascular system fails to perfuse tissues, cells, and organs adequately, resulting in widespread impairment of cellular metabolism and tissue function. **Tissue perfusion** is defined as the adequacy of blood flow through the small vessels of the extremities to maintain tissue function.[1] Tissue perfusion can be disrupted by any factor that alters delivery of blood to cells and tissues and increases oxygen consumption, such as decreased cardiac output, blood volume, or blood pressure. Shock has many causes and clinical manifestations related to the type of shock. Ultimately, shock from any cause will progress to organ failure and death, unless physiologic mechanisms reverse the process or clinical intervention succeeds in stopping the progression. Untreated, severe shock overwhelms the body's compensatory mechanisms that may result in multisystem organ failure.

Multiple organ dysfunction syndrome (MODS) is progressive and often involves the ultimate failure of two or more organ systems after a severe illness or injury. The disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops. For many years the syndrome was referred to as *multiple organ failure* or *multiple systems organ failure.* Gradually it was recognized that the term *organ dysfunction* more accurately describes the syndrome as a process of physiologic deterioration.

Major burns result in extensive immediate tissue injury and thus are a form of trauma with wide-reaching effects on all organ systems. The cause of injury may be thermal contact, flame, chemical agents, or electrical agents; each cause requires a different approach in diagnosis and treatment. Closely associated with thermal burns is smoke inhalation injury, which accounts for about 25% of all burn unit admissions. As a multiorgan problem, thermal injuries can have an overwhelming effect on survival of the burned individual. Regardless of the cause of burns, the result is a final common pathway of physiologic response dependent on the extent of burn surface involvement and the depth of tissue destruction.

SHOCK

Shock can be classified by type, principal pathophysiologic process, or clinical manifestations. Classification by type is perhaps the most useful because it suggests the cause and pathophysiologic process of the underlying disorder, which must be treated

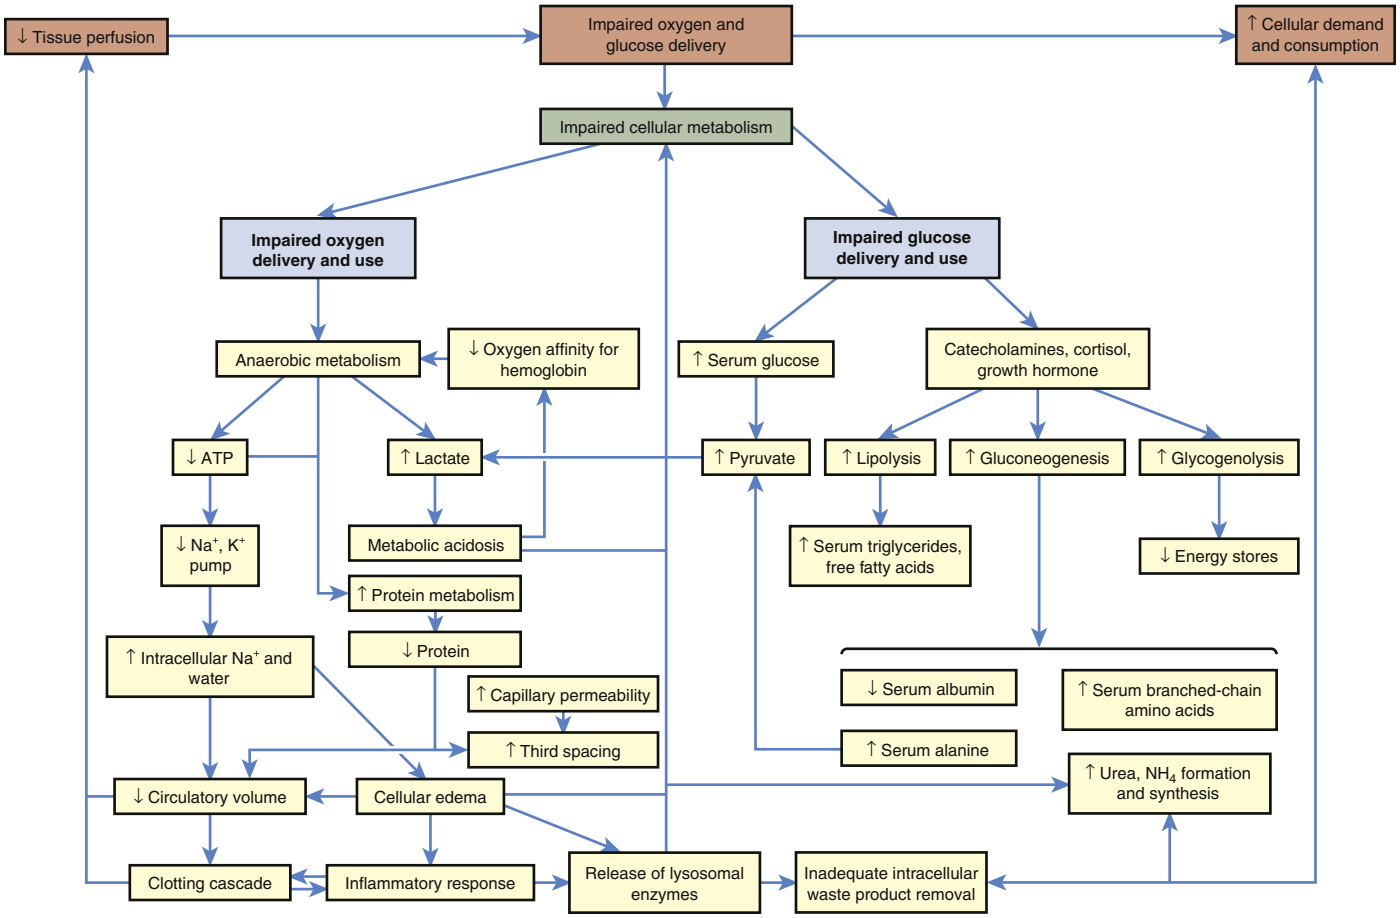

FIGURE 48-1 Impairment of Cellular Metabolism by Shock. *ATP,* Adenosine triphosphate.

to prevent the irreversible cellular alterations and impairment of cellular metabolism. **Shock** is classified as cardiogenic (caused by heart failure); neurogenic or vasogenic (caused by alterations in vascular smooth muscle tone); anaphylactic (caused by hypersensitivity); septic (caused by infection); or hypovolemic (caused by insufficient intravascular fluid volume).

Cellular Alterations and Impairment of Cellular Metabolism

The body consists of many organs, tissues, and cells that may function or malfunction at different stages of metabolic impairment. The common pathway in all types of shock is impairment of cellular metabolism, attributable to decreased delivery of oxygen and nutrients, frequently coupled with an increased demand and consumption of oxygen and nutrients and a decreased removal of cellular waste products.[2] Figure 48-1 illustrates the pathophysiology of shock at the cellular level.

Impairment of Oxygen Delivery and Use

In all types of shock, the cells do not receive adequate amounts of oxygen because of decreased delivery or increased cellular consumption, or both, and are therefore unable to use oxygen normally (see Figure 48-1). In cardiogenic shock cardiac output is too low to deliver adequate oxygen to the cell. In hypovolemic shock, oxygen delivery is impaired by inadequate numbers of red cells that carry oxygen and inadequate blood volume. In neurogenic, anaphylactic, and septic shock, systemic vascular resistance (SVR) becomes very low because of vasodilation, resulting in inadequate perfusion pressure in the capillaries. Thus, the pressure needed to drive oxygen and nutrients across cell membranes is inadequate. In septic shock, hypoxia is worsened by increased inflammatory responses, such as fever, that increase the cell's oxygen demand and consumption rate, and by direct toxic and inflammatory chemical disruption of cellular metabolism, that impairs the cells' ability to use oxygen.

Both positive and negative compensatory mechanisms, such as anaerobic metabolism, lysosomal enzyme release, decreased intravascular volume, and activation of the clotting cascade, may further impair oxygen delivery and use. Anaerobic metabolism results in disruption of electrolyte and lysosomal enzymatic processes, thus changing the normal ionic and osmotic levels in cells governed by the physical law of diffusion. Diffusion of nutrients and wastes into and out of the cell takes longer, and cellular metabolism is further altered. Without oxygen, the cell shifts from aerobic to anaerobic metabolism. Anaerobic metabolism is a less efficient method of extracting energy from carbon bonds, and the cell begins to use adenosine triphosphate (ATP) faster than it can be replaced. Without ATP the cell loses its ability to maintain an electrochemical gradient across its selectively permeable membrane. Specifically, the cell cannot operate the

sodium-potassium pump. Sodium and chloride accumulate inside the cell and potassium exits the cell. Cells of the nervous system and myocardium are profoundly and immediately affected. The resting potentials of these cells are reduced, and the action potentials decrease in amplitude (see Chapter 1). Myocardial depressant factor also decreases the contractility of the heart. A variety of clinical manifestations of impaired central nervous system and myocardial function result.

As sodium moves into the cell, water follows. Throughout the body, the water drawn from the interstitium into the cells is "replaced" by water that is in turn drawn out of the vascular space, often called "third spacing" of fluid. This decreases circulatory volume. Within the cells, water causes cellular edema that disrupts cellular membranes, releasing lysosomal enzymes that injure the cells internally and leak into the interstitium.

In addition to decreasing ATP stores, anaerobic metabolism affects the pH of the cell, and metabolic acidosis develops. A compensatory mechanism is initiated that enables cardiac and skeletal muscles to use lactic acid as a fuel source, but only for a limited time. The decreasing pH of the cell that is functioning under anaerobic conditions has serious consequences. Enzymes necessary for cellular function dissociate under acidic conditions. Enzyme dissociation stops cell function, repair, and division. As lactic acid is released systemically, blood pH drops, reducing the oxygen-carrying capacity of the blood (see Chapter 2), and the heart's ability to pump. Therefore, less oxygen is delivered to the cells and further hypoxia results in acidosis, which triggers more lysosomal enzyme release caused by disruption of lysosomal membrane integrity. Lysosomal enzymes released during shock injure the cell that released them and injure adjacent cells. By damaging the mechanisms of surrounding cells, lysosomal enzymes extend areas of impaired metabolism and cellular injury.

Intravascular fluid loss into the intracellular and interstitial spaces, described as "third spacing" earlier, is amplified when serum albumin and other plasma proteins are consumed for fuel, which results in decreased intravascular osmotic pressure, shift of fluid to the interstitial or extracellular spaces, and decreased circulatory volume. Decreased circulatory volume magnifies decreased tissue perfusion in all types of shock. Decreased intravascular volume causes decreased cardiac output in septic shock and further reduces cardiac output in cardiogenic shock. In individuals with anaphylactic, neurogenic, or septic shock and an already dilated vasculature, hypotension worsens as a result of decreased circulatory volume. New data on additional mechanisms for hypotension (vasodilation) are illustrated in Figure 48-7 (p. 1678).

Concurrently, diffusion across capillary membranes occurs more slowly, as blood flow in the capillary beds becomes sluggish, caused by decreased fluid volume with increased viscosity of blood. Sluggish capillary flow decreases tissue perfusion further, microvascular clots form, and activation of the clotting cascade may begin (see Chapter 27). Microemboli formation and platelet aggregation account for common complications of shock, such as acute tubular necrosis, acute respiratory distress syndrome (ARDS), and disseminated intravascular coagulation (DIC). It also may activate or be activated by the inflammatory response.[3]

Impairment of Glucose Delivery and Use

Impaired glucose use can be caused by either impaired glucose delivery or impaired glucose uptake by the cells (see Figure 48-1). The reasons for inadequate glucose delivery are the same as those enumerated for inadequate oxygen delivery. In addition, in septic and anaphylactic shock, glucose metabolism may be increased or disrupted because of fever or bacteria, and glucose uptake can be prevented by the presence of vasoactive toxins, endotoxins, histamine, and kinins.

Some of the compensatory mechanisms activated by shock contribute to decreased glucose uptake and use by the cells. High serum levels of cortisol, growth hormone, and catecholamines account for hyperglycemia and insulin resistance, tachycardia, increased SVR, and increased cardiac contractility. Cells shift to glycogenolysis, gluconeogenesis, and lipolysis to generate fuel for survival (see Chapter 1). Except in the liver, kidneys, and muscles, the body's cells have extremely limited stores of glycogen. In fact, total body stores can fuel the metabolism for only about 10 hours. The depletion of fat and glycogen stores is not itself a cause of organ failure, but the energy costs of glycogenolysis and lipolysis are considerable and contribute to the cellular failure.

The depletion of protein is, however, a cause of organ failure. When gluconeogenesis causes proteins to be used for fuel, these proteins are no longer available to maintain cellular structure, function, repair, and replication. The breakdown of protein occurs in starvation states, hyperdynamic metabolic states, and septic shock. Under anaerobic metabolism, protein breakdown liberates alanine, which is converted to pyruvate. Pyruvic acid is changed into lactic acid, leading to an increased affinity for oxygen to bind to hemoglobin with resultant hypoxia and metabolic acidosis.

As proteins are metabolized anaerobically, ammonia and urea are produced. Ammonia is toxic to living cells. Uremia develops, and uric acid further disrupts cellular metabolism. Proteins are broken down preferentially. Serum albumin and other plasma proteins are consumed for fuel first. Serum protein consumption decreases capillary osmotic pressure and contributes to the development of interstitial edema, creating another negative compensatory outcome that decreases circulatory volume. In septic shock, plasma protein breakdown includes breakdown of immunoglobulins, thereby impairing immune system function when it is most needed.

Muscle wasting caused by protein breakdown weakens skeletal and cardiac muscle. Skeletal muscle wasting impairs the muscles that facilitate breathing. Muscle wasting therefore alters the actions of both heart and lungs. The delivery of oxygen and glucose to the cells is directly reduced, as is the removal of metabolic waste products, such as the formation of carbon dioxide and lactic acid, causing metabolic acidosis with resultant inability of muscles, organs, and tissues to function mechanically and electrically.

The metabolic wastes that accumulate in the cell and interstitial spaces are toxic to the cells and further disrupt cellular function and membrane integrity. In septic shock, for example, a deficiency in cellular metabolism and the buildup of toxins may precede and cause decreased tissue perfusion.

Types of Shock, Clinical Manifestations, and Treatment

Each type of shock (cardiogenic, hypovolemic, neurogenic, anaphylactic, septic) involves numerous clinical manifestations, signs, and symptoms that also may characterize other conditions, making diagnosis difficult. An individual's history and situation are correlated with the specificity of the shock state suspected or anticipated. Clinical manifestations common in septic shock are fever, high heart rate, high respiratory rate, or elevations in immune responses, such as increased levels of white blood cells and circulating blood glucose. Subjective complaints often are nonspecific and general. The individual may report feeling sick, weak, cold, hot, nauseated, dizzy, confused, afraid, thirsty, and short of breath.

The initial management for shock is to discover, diagnose, and correct or remove the underlying cause. Although this seems a simple tenet, it is one that is not always remembered. Thus treatment for cardiogenic shock begins with diagnosis and treatment of heart failure or at least enhancement of cardiac output. If hypovolemia is the cause of shock, hemorrhage and other causes of fluid loss must be stopped. In neurogenic shock, as a result of spinal cord trauma, stabilization of the spine and surrounding tissue is an initial approach and pain usually can be decreased to a level at which neutrally-mediated decreases of SVR cease. The initial treatment for anaphylactic shock is to remove or neutralize the antigen. Treatment for septic shock begins with eradication of the infective agent, usually with antimicrobials.

Simultaneous to correcting the underlying cause or condition, treatment is directed at targeting improvement of microcirculatory tissue perfusion.[4] Optimizing oxygenation is an absolute necessity in all shock states. The goal has a dual purpose to both optimize oxygen delivery and reduce oxygen consumption. Intravenous fluid is administered to expand intravascular volume and thereby improve tissue perfusion by increasing blood pressure and cardiac output, except in cases of cardiogenic shock, which require diuresis to reduce preload.

Effective glucose level control in various shock states has been shown to improve outcomes. Hyperglycemia, caused by insulin resistance in the liver and muscle, is a common finding in the critically ill. This is most likely an adaptive response providing glucose for the brain, red blood cells, and wound healing. The extent of appropriate glucose level control has been evaluated in recent years, leading to more aggressive treatment with continuous, titrating insulin infusions to maintain blood glucose levels closer to normal, thus promoting normal cellular function and healing.[5]

Once cellular and organ dysfunction and physiologic derangement are established, risk of morbidity and mortality increases. Prevention and early treatment offer the best prognosis.

Cardiogenic Shock

Cardiogenic shock results from the inability of the heart to pump adequate blood to tissues and end organs from any cause, the most common being the short-term consequences of an acute myocardial infarction or a severe episode of myocardial ischemia. **Cardiogenic shock** is defined as persistent hypotension and tissue hypoperfusion caused by cardiac dysfunction in the presence of adequate intravascular volume and left ventricular filling pressure.[6] Pathologic conditions that reduce contractility, cause pump failure, impair diastolic filling, or cause obstruction can lead to cardiogenic shock. Decreased contractility and pump failure can result from (1) acute myocardial infarction (AMI), cardiomyopathy, sepsis, myocarditis, pericarditis, aneurysm, dysrhythmias, contusion, metabolic abnormalities, papillary muscle rupture; (2) impaired diastolic filling related to dysrhythmias; and (3) obstruction attributable to pulmonary embolism, cardiac tamponade, valvular disorders, tumors, and wall rupture or defects.[7]

Overall hospital mortality because of cardiogenic shock has decreased from approximately 90% in the 1970s to a recent estimate of 50%.[8]

As cardiac output decreases, compensatory adaptive responses are activated, such as the renin-angiotensin, neurohormonal, and sympathetic nervous systems, that lead to fluid retention, systemic vasoconstriction, and tachycardia.[9] Activation of the inflammatory response (resulting in expression of inducible nitric oxide synthase), activation of inflammatory cytokines, and activation of the complement system appear to play an important role in the pathogenesis and outcome of cardiogenic shock.[10] Increases in contractility, heart rate, and blood pressure are maintained in mild shock states through vasoconstriction in response to catecholamine release from the adrenals. Vasoconstriction increases vascular resistance to normalize blood pressure and increases cardiac performance by returning more blood volume and increasing perfusion to the heart; however, this increases myocardial demand and consumption of oxygen and nutrients by the heart. Increasing myocardial requirements burden the already failing heart, which can no longer pump an adequate volume of blood with sufficient force to perfuse the tissues. Thus increased coronary, tissue, and cellular ischemia further deteriorates myocardial function and shock.

Mortality in cardiogenic shock is reduced by use of intra-aortic balloon counterpulsation (IABP); cardiosupportive drug regimens and early coronary interventions have also improved outcomes.[10-12] Following myocardial infarction, reperfusion and revascularization can be achieved with treatment modalities that include fibrinolytic therapies (medications that disintegrate the coronary thrombus) and percutaneous interventions (balloon angioplasty, stent placement, and thrombectomies). Surgery (coronary artery bypass, ventriculoplasty, or heart transplant) is also utilized to open the coronary vessels during an acute myocardial infarction or to replace irreparable heart muscle. Cardio-supportive drug and fluid regimens are initiated to maintain adequate blood pressure and essential fluid and electrolyte balance, and to optimize coronary perfusion to the myocardium. Mechanical assist devices, specifically intra-aortic balloon pumps and percutaneous or ventricular assist devices (VADs), are used to support cardiac output temporarily until the individual improves or transplantation is possible.[11] Implantable VADs, pacemakers, or internal defibrillator devices are sometimes used as permanent treatment

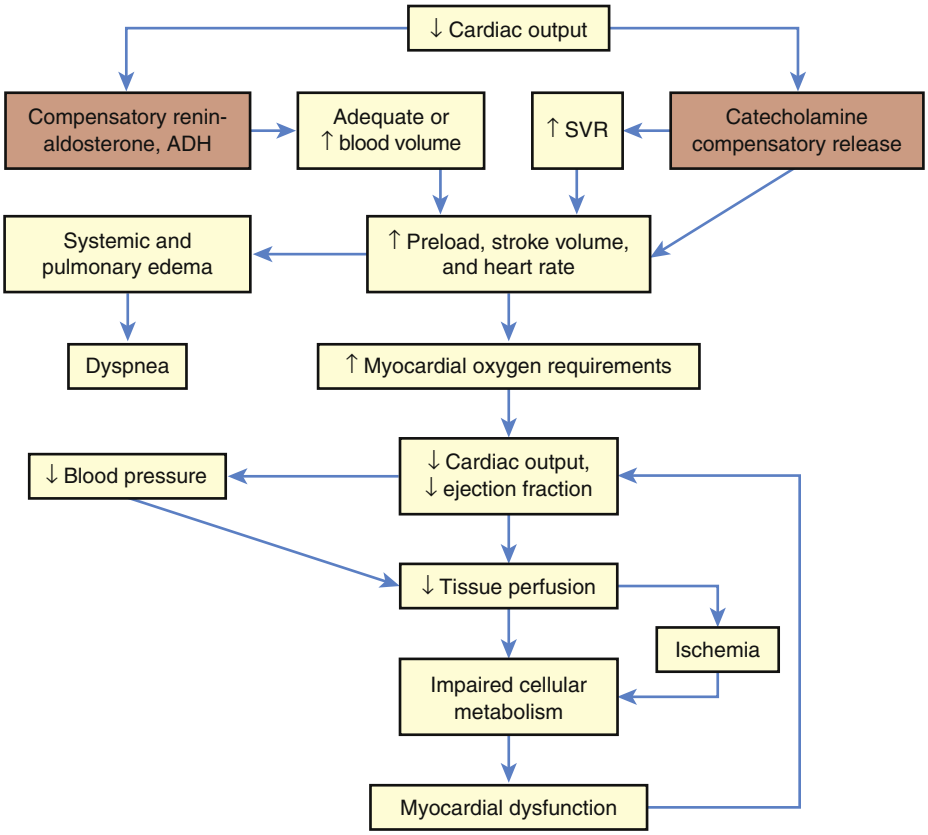

FIGURE 48-2 Cardiogenic Shock. Shock becomes life threatening when compensatory mechanisms (orange boxes) cause increased myocardial oxygen requirements. *ADH,* Antidiuretic hormone; *SVR,* systemic vascular resistance.

for those who survive cardiogenic shock. Continuous hemodynamic monitoring should be employed to evaluate vascular volume and pressures, optimize fluid levels, and monitor drug administration with the goal of improving cardiac output and tissue perfusion.[13]

The clinical manifestations of cardiogenic shock are caused by inadequate perfusion to the heart and end organs (Figure 48-2). Subjective complaints of chest pain, dyspnea, and faintness, along with feelings of impending doom, are often revealed. Classic observable signs and symptoms of tachycardia, tachypnea, hypotension, jugular venous distention, dysrhythmia, and low measured cardiac output are hallmarks. Cyanosis; skin mottling; rapid, faint, or irregular pulses; low urine output; and occasional peripheral edema are additional signs and symptoms of end-organ hypoperfusion. Myocardial dysfunction from fluid overload may result in extra heart sounds, pulmonary edema, hypoxemia, and elevated end-organ laboratory values. The amount of brain natriuretic peptide, produced when the heart stretches in relation to increased volume with decreased cardiac output, is increased to help diurese the fluid volume excess.[9] Pulmonary edema increases as volume accumulates and expands from the heart into the lungs as evidenced by audible crackles and wheezes as well as abnormal vascular congestion on chest radiography. Metabolic abnormalities involving electrolyte imbalances and elevated levels of inflammatory markers may result from or concur with the cardiac cascade of shock.

Hypovolemic Shock

Hypovolemic shock is caused by loss of whole blood (hemorrhage), plasma (burns), or interstitial fluid (diaphoresis, diabetes mellitus, diabetes insipidus, emesis, or diuresis) in large amounts. Loss of whole blood or plasma causes hypovolemia directly. Loss of interstitial fluid causes an indirect "relative" hypovolemia by promoting diffusion of plasma from the intravascular to the extravascular space. Hypovolemic shock begins to develop when intravascular volume has decreased by about 15%.

Hypovolemia is offset initially by compensatory mechanisms (Figure 48-3). Heart rate and SVR increase as a result of catecholamine release by the adrenals. This boosts cardiac output and tissue perfusion pressures. Compelled by a decrease in capillary hydrostatic pressures, interstitial fluid moves into the vascular compartment. The liver and spleen add to blood volume by disgorging stored red blood cells and plasma. In the kidneys, renin (through several intermediaries) stimulates aldosterone release and the retention of sodium (and hence water), whereas antidiuretic hormone (ADH, or vasopressin) from the posterior pituitary gland increases water retention. Data on the compensation of ADH, however, show that as shock worsens, ADH in plasma decreases. Hypovolemic shock results in compensatory vasoconstriction and increased SVR and afterload in order to improve blood pressure and perfusion to core organs of the body.

These compensatory mechanisms are, however, finite. If the initial fluid or blood loss is great or if loss continues,

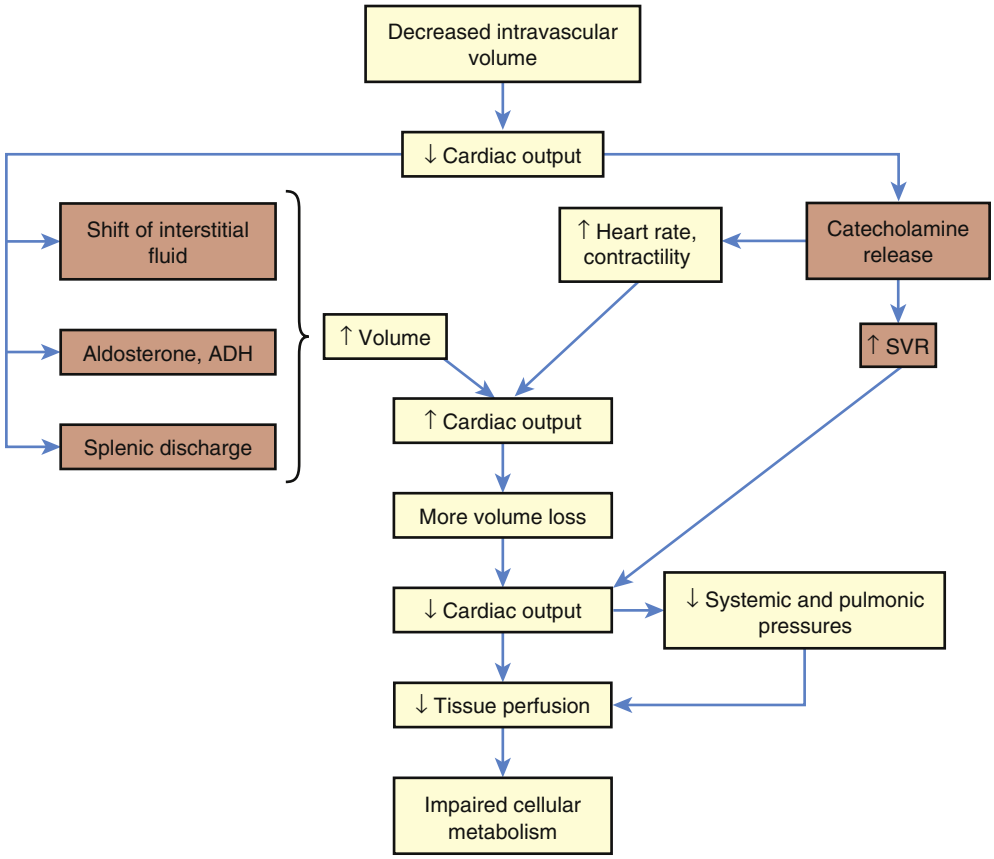

FIGURE 48-3 Hypovolemic Shock. This type of shock becomes life threatening when compensatory mechanisms *(orange boxes)* are overwhelmed by continued loss of intravascular volume. *ADH,* Antidiuretic hormone; *SVR,* systemic vascular resistance.

compensation fails, resulting in decreased tissue perfusion. Nutrient delivery to the cells is impaired, and cellular metabolism fails. Mortality from traumatic hemorrhagic shock ranges from 10% to 31%. Prompt control of hemorrhage is the treatment of choice. Fluid replacement is also important, but the type of fluid to be used and the rate of replacement are controversial.[14,15] The clinical manifestations of hypovolemic shock include high SVR, poor skin turgor, increased thirst, oliguria, low systemic and pulmonary preloads, and rapid heart rates.

Neurogenic Shock

Neurogenic shock also is called **vasogenic shock.** Both terms refer to a widespread and massive vasodilation that results from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle (see Chapter 31). Occasionally, parasympathetic overstimulation or sympathetic understimulation persists, causing vasodilation for an extended period. Extreme, persistent vasodilation leads to neurogenic shock (Figure 48-4). Neurogenic shock creates "relative hypovolemia." Blood volume has not changed, but the amount of space containing the blood has increased, so that SVR decreases drastically; thus pressure in the vessels is inadequate to drive nutrients across capillary membranes, and nutrient delivery to the cells is impaired. As with other types of shock, this leads to impaired cellular metabolism.

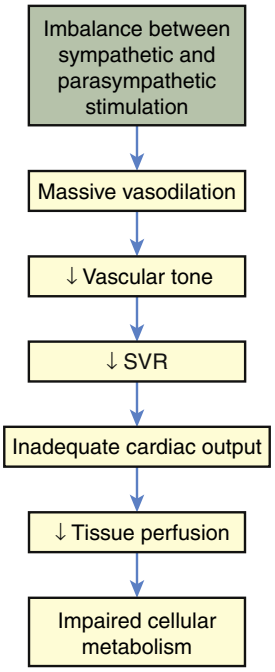

FIGURE 48-4 Neurogenic Shock. *SVR,* Systemic vascular resistance.

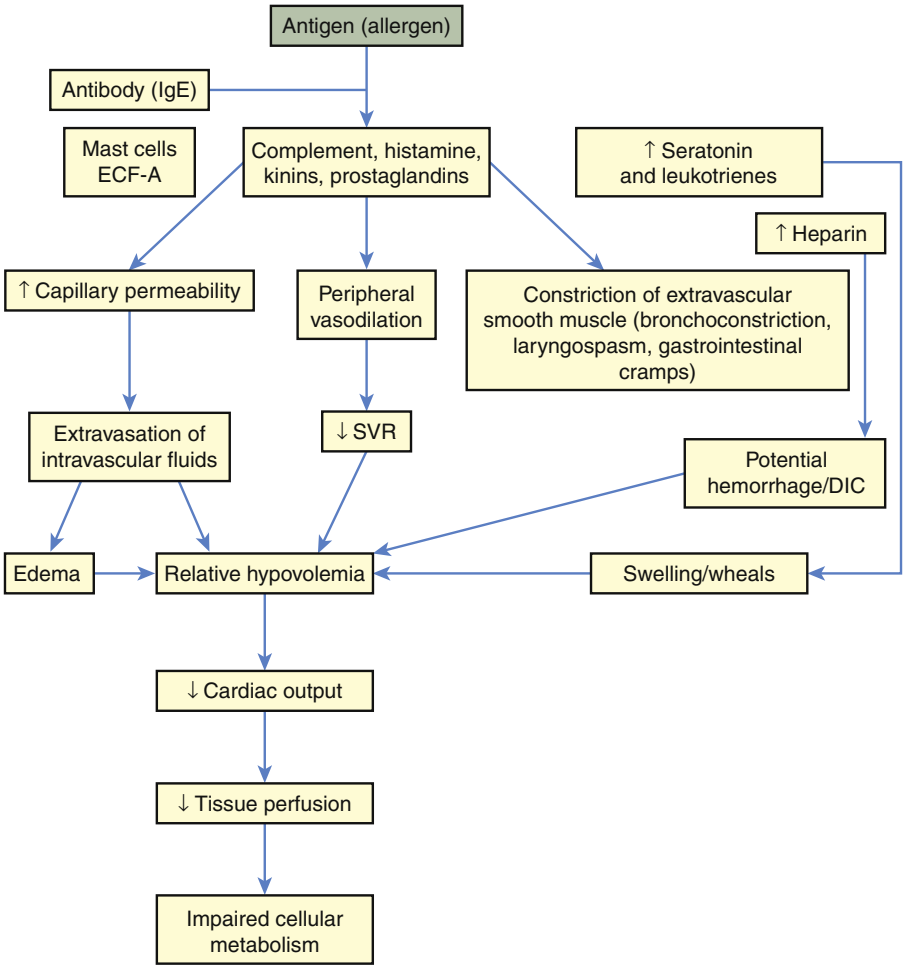

FIGURE 48-5 Anaphylactic Shock. *DIC,* Disseminated intravascular coagulation; *ECF-A,* eosinophil chemotactic factor anaphylaxis; *IgE,* immunoglobulin E; *SVR,* systemic vascular resistance.

Neurogenic shock can be caused by any factor that stimulates parasympathetic activity or inhibits sympathetic activity of vascular smooth muscle. (Parasympathetic stimulation automatically inhibits sympathetic activity and vice versa; see Chapter 31.) Normally, sympathetic stimulation maintains muscle tone. If sympathetic stimulation is interrupted or inhibited, vasodilation occurs. Therefore, trauma to the spinal cord or medulla, conditions that interrupt the supply of oxygen to the medulla, or conditions that deprive the medulla of glucose (e.g., insulin reactions) can cause neurogenic shock by interrupting sympathetic activity. Depressive drugs, anesthetic agents, and severe emotional stress and pain are other causes of neurogenic shock.

The clinical hallmark of neurogenic shock is a very low SVR, along with other indicators of excessive parasympathetic activity. Bradycardia is the most obvious manifestation, especially in the early stages. Bradycardia may cease when compensatory mechanisms, particularly an increase in sympathetic system activity, have been initiated. The ejection fraction remains high, indicating a healthy myocardium, whereas central venous pressure decreases as the veins dilate. Neurogenic shock causes fainting if blood pressure decreases to the point that cerebral metabolism is not sufficient to support consciousness. Most episodes of fainting are *not* shock, however; for such episodes to progress to shock is rare. By allowing the blood pressure to equalize from head to toe as the individual becomes prone, fainting can actually prevent shock.

Anaphylactic Shock

Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers a reaction known as *anaphylaxis.* (An allergen is an antigen to which an individual is hypersensitive; see Chapters 7, 8, and 9 for discussions of immunity, inflammation, and hypersensitivity.) Immunologic causes are related to the inflammatory and vasodilatory effects triggered by a pathologic allergic reaction to an antigen. Production of mast cells, IgE, and low-affinity IgE receptor (FceRI) is induced by cellular response to the antigen. *Anaphylactoid* type reactions, which are nonimmunologic in origin, can be related to cold weather, exercise, and contaminants in medications.[16] Physiologic alterations related to the inflammatory and immune response, similar to neurogenic shock, are massive—vasodilation, peripheral pooling, and relative hypovolemia lead to decreased tissue perfusion and impaired cellular metabolism (Figure 48-5). Anaphylactic shock is often severe and has immediate symptoms, including an itchy rash, throat swelling,

and low blood pressure, related to the massive vasodilation and systemic inflammation that may progress to death in minutes if emergency treatment is not rendered.

Some allergens known to cause hypersensitivity reactions are foods, insect and snake venoms, pollens, medications, and latex. Once in the body, the allergen causes the extensive immune and inflammatory response. The vascular effects of this response include vasodilation and increased vascular permeability, resulting in peripheral pooling and tissue edema. The extravascular effects include constriction of extravascular smooth muscle. Constriction often causes respiratory difficulty because it tends to affect smooth muscle layers in the airway walls (e.g., the larynx and bronchioles; see Chapter 34).

Clinical manifestations of anaphylactic and anaphylactoid shock may be anxiety, difficulty in breathing, gastrointestinal cramps, edema, hives (urticaria), sensations of burning or itching of the skin, fever, and hemolysis. A precipitous decrease in blood pressure occurs and is followed by impaired mentation. Other signs include decreased SVR (with high or normal cardiac output) and oliguria. Treatment begins with removal of the antigen (if possible). Epinephrine is administered to decrease mast cell and basophil degranulation, cause vasoconstriction, and reverse airway constriction.[17] Volume expanders (e.g., lactated Ringer solution) are given intravenously to reverse the relative hypovolemia, and antihistamines and corticosteroids are given to stop the inflammatory reaction.

In response to the need for improved anaphylaxis diagnosis and treatment, the World Allergy Organization (WAO) formulated global guidelines in 2011 for assessment and management of anaphylaxis.[17] These guidelines were further updated in 2012 to include recommendations for validation of the clinical criteria for diagnosis, use of epinephrine, development of in vitro tests to distinguish clinical risk from asymptomatic sensitization, and immune modulation to prevent anaphylaxis[16] (see What's New? Anaphylactic Shock).

Septic Shock

Septic shock is the endpoint of a continuum of progressive dysfunction.[18] The syndrome begins with systemic inflammatory response syndrome (SIRS), then sepsis, then severe sepsis, and then septic shock. Consensus on definitions of each component was updated at an international sepsis conference in 2003 (Table 48-1).[18] The International Sepsis Forum reviewed research for sepsis to identify and define the six most common infection sites (pneumonia, bloodstream, intravascular catheter, intra-abdominal, urosepsis, and surgical wound infection) associated with sepsis in the intensive care setting.[19]

Severe sepsis is the tenth most common cause of death in the United States.[20] Mortality ranges from 28% to 60%.[21] Septic shock is caused by gram-negative bacteria, gram-positive bacteria, and fungi. Advances in antibiotic therapy for gram-negative sepsis have made gram-positive bacteria the leading cause of sepsis.[22] Even when properly treated with available therapies, it carries a high mortality rate. Prognosis is significantly affected by the source and virulence of the infectious microorganism.

WHAT'S NEW?

Anaphylactic Shock

In response to the need for improved anaphylaxis diagnosis and treatment, the World Allergy Organization (WAO) formulated global guidelines in 2011 for assessment and management of anaphylaxis. These guidelines were further updated in 2012 to include recommendations for validation of the clinical criteria for diagnosis, use of epinephrine, development of in-vitro tests to distinguish clinical risk form asymptomatic sensitization, and immune modulation to prevent anaphylaxis.

Data from Simons FE et al: *Curr Opin Allergy Clin Immunol* 12(4): 389–399, 2012.

Septic shock begins with a nidus of infection that may be readily discernible or extremely difficult to locate (Figure 48-6). Bacteria and fungi enter the bloodstream to produce bacteremia in one of two ways: (1) directly from the site of infection, or (2) indirectly from toxic substances released by the bacteria directly into the bloodstream. These toxic substances, which act as triggering molecules in the septic syndrome, include endotoxins released by gram-negative microorganisms, lipoteichoic acids and peptidoglycan released by gram-positive microorganisms, and superantigens.[22]

The triggering molecules cause the host to initiate a proinflammatory response. Proinflammatory cells released include polymorphonuclear leukocytes, macrophages, monocytes, and platelets. Proinflammatory mediators released include cytokines (interleukins [IL]-1, IL-2, IL-6, IL-8, and IL-15; tumor necrosis factor-alpha [TNF-α]; and granulocyte cell–stimulating factor), complement and complement cascade activation, kinins, arachidonic acid metabolites (prostaglandins, prostacyclin, leukotrienes, and thromboxane), soluble adhesion molecules, platelet-activating factor, endorphins, vasoactive neuropeptides, histamine, serotonin, monocyte chemoattractant proteins 1 and 2, proteolytic enzymes (e.g., elastase and lysosomal enzymes), protein kinase, tyrosine kinase, CD14, toxic oxygen metabolites (e.g., superoxide, hydroxyl radical, hydrogen peroxide, peroxynitrite), neopterin, and clotting cascade activation.[3,23,24] Proinflammatory cytokines enhance tissue factors, which initiates coagulation. Diminished thrombomodulin (cell surface glycoprotein of endothelial cells) inhibits the conversion of protein C and activated protein C. A compensatory anti-inflammatory response syndrome is presumed to follow this response.[3,23,24] Anti-inflammatory mediators released include lipopolysaccharide-binding protein; IL-1 receptor antagonist; soluble CD-14; type 2 IL-1 receptor; leukotriene B_4 receptor antagonist; IL-4, IL-10, and IL-13; soluble tumor necrosis factor receptor; transforming growth factor-beta (TGF-β); epinephrine; and nitric oxide.[3,23,24] Presumably the end result is a mixed antagonistic response syndrome as proinflammatory and anti-inflammatory mediators respond, intensify, and lead the host into MODS.

Clinical manifestations of septic shock are persistent low arterial pressure, low SVR from vasodilation, and an alteration in oxygen extraction by all cells. Septic shock and states of prolonged shock causing tissue hypoxia with lactic acidosis increase nitric oxide synthesis, activate ATP-sensitive and

TABLE 48-1 DEFINITIONS OF SEPTIC SHOCK COMPONENTS

TERM	BASIC DEFINITION	COMMENTS
Infection	A pathologic process that results from an invasion of a normal part of the body by pathogenic or potentially pathogenic microorganisms	Still viewed as an imperfect definition Infection can be strongly suspected without microbiologic confirmation
Bacteremia	Presence of viable bacteria in the blood	Neither necessary nor sufficient to make a diagnosis of sepsis
SIRS	Systemic inflammatory response syndrome is manifested by two or more of general variables: 1a through 1d or 2a through 2c	*Diagnostic criteria:* 1. General variables a. Fever—core temperature >38.3° C (100.9° F) b. Hypothermia—core temperature <36° C (96.8° F) c. Heart rate >90 beats/minute d. Tachypnea e. Altered mental status f. Significant edema or positive fluid balance (>20 ml/kg over 24 hr) g. Hyperglycemia (blood sugar >140 mg/dl) in the absence of diabetes 2. Inflammatory variables a. Leukocytosis (WBC count >12,000) b. Leukopenia (WBC count <4000) c. Normal WBC with >10% immature forms d. Plasma C-reactive protein >2 SD above the normal value e. Plasma procalcitonin >2 SD above the normal value 3. Hemodynamic variables a. Arterial hypotension (SBP <90 mmHg; MAP <70, or an SBP decrease >40 mmHg) b. $S\bar{v}O_2$ >70% c. Cardiac index >3.5 L/min 4. Organ dysfunction variables a. Arterial hypoxemia (PaO_2/FiO_2 <300) b. Acute oliguria (urine output <0.5 ml/kg/hr or 45 ml for at least 2 hr) c. Creatinine increase >0.5 mg/dl d. Coagulation abnormalities (INR >1.5 or a PTT >60) e. Ileus f. Thrombocytopenia (platelet count <100,000) g. Hyperbilirubinemia (plasma total bilirubin >4 mg/dl or 70 mmol/L) 5. Tissue perfusion variables a. Hyperlactatemia (>1 mmol/L) b. Decreased capillary refill or mottling
Sepsis	Systemic response to infection, which is manifested by two or more of the SIRS criteria	
Severe sepsis	Sepsis complicated with one or more organ system dysfunctions	May be difficult to differentiate underlying organ dysfunction from sepsis-related organ dysfunction
Septic shock	Severe sepsis complicated by persistent hypotension refractory to early fluid therapy	Persistent systolic blood pressure <90 mmHg

Data from Dellinger RP et al: *Crit Care Med* 41(2):580–637, 2013; Levy MM et al: *Crit Care Med* 312:1250, 2003; Opal SM, *Scand J Infect Dis* 35:529, 2003.

INR, International normalized ratio; *MAP,* mean arterial pressure; *Pao_2/FiO_2,* partial pressure of oxygen in arterial blood/fraction of inspired oxygen; *PTT,* partial thromboplastin time; *SD,* standard deviation; *SBP,* systolic blood pressure; $S\bar{v}0_2$, saturation of hemoglobin with oxygen; *WBC,* white blood cell.

calcium-regulated potassium channels (K_{ATP} and K_{Ca}, respectively) in vascular smooth muscle (see Chapter 31), and lead to depletion of ADH (vasopressin) (Figure 48-7). Tachycardia causes cardiac output to remain normal or become elevated, although myocardial contractility is reduced. Temperature instability is present, ranging from hyperthermia to hypothermia. Effects on other organ systems may result in deranged renal function, gastrointestinal mucosa changes that result in release of bacteria from the gut, jaundice, clotting abnormalities, deterioration of mental status, and tachypnea that often progresses to ARDS.

Early detection of high-risk illness and rapid implementation of the following standard protocols are increasingly being used by hospitals worldwide: decreasing the time before lactate levels are determined; obtaining blood cultures; starting administration of antibiotics and antifungals; implementing a fluid challenge; achieving goals for blood pressure, central venous pressure (CVP), and central venous oxygen saturation.[25,26] Promptly initiated treatment helps reduce mortality and morbidity related to multiple organ dysfunction. Infection and sepsis identified in the early stages and treated with antibiotics and fluid resuscitation may prevent evolution to severe sepsis and shock; however, once these are identified, more stringent treatment is recommended. The current guidelines for severe sepsis and septic shock[27] recommend immediate resuscitation in patients with lactate levels >4 mmol/L. Elevated lactate levels indicate tissue hypoperfusion and patients should begin early goal-directed therapy or fluid resuscitation within 6 hours, regardless of blood pressure

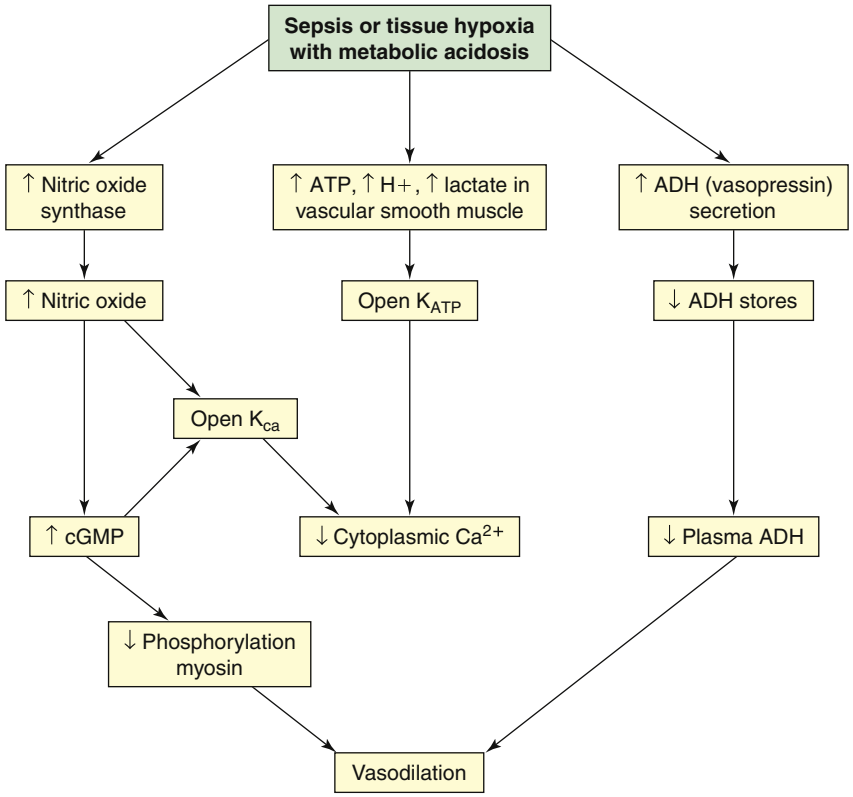

FIGURE 48-7 Mechanisms of Vasodilation in Shock. Vasodilatory shock is caused by the inappropriate activation of vasodilatory mechanisms and the failure of constrictor mechanisms. Unregulated nitric oxide, by regulating guanylate cyclase and generating cyclic guanosine monophosphate (cGMP), causes dephosphorylation of myosin and, thus, vasodilation. Nitric oxide synthesis and metabolic acidosis activate the potassium channels (K_{ATP} and K_{ca}) in the plasma membrane of vascular smooth muscle. The resulting hyperpolarization (see Chapter 3) of the membrane presents the calcium that mediates norepinephrine and angiotensin II–induced vasoconstriction from entering the cell. Therefore, hypotension and vasodilation stubbornly persist despite high plasma levels of these hormones. In contrast, and unexpectedly, the plasma level of antidiuretic hormone (ADH) (vasopressin) is low despite the presence of hypotension. The early, massive release of ADH may result in future depletion.

level.[25,26] Specifically, fluid resuscitation with either crystalloid or colloid fluids should be goal-directed to maintain the following values: central venous pressure, 8 to 12 mmHg (or 12 to 15 mmHg when the patient is being mechanically ventilated); mean arterial pressure, 65 mmHg; urine output, 0.5 ml/kg/hr; mixed venous saturation ($S\bar{v}O_2$), 65%. In addition, specific anatomic sites of infection with source identification should be determined so that appropriate antibiotics can be prescribed and control measures can be implemented that eliminate or reduce the spread of infection.[27,28] Fungal assays, including 1,3-β-D-glucan assay and mannan and anti-mannan antibody assays, are recommended to identify suspected fungal infection.[29] Normal saline, at least 1 L or 30 ml/kg body weight, is the initial fluid of choice and hetastarches with molecular weights >200 daltons are not recommended. Adequate and incremental fluid resuscitation is a prerequisite and should be continued to achieve perfusion; supplementation with vasopressors is recommended if the endpoints of tissue perfusion (CVP and normalized lactate levels) are not met.[29]

Pharmacologic hemodynamic support and adjunctive therapy to maintain tissue perfusion include vasoactive agents. Norepinephrine is now considered the initial vasopressor of choice.[29] Dopamine, epinephrine, phenylephrine, and vasopressin are alternatives; however, these are less preferred because of potential tachycardia, dysrhythmias, or reduction in splanchnic blood flow. Dobutamine, an inotropic agent, should be used if myocardial dysfunction is present or hypotension remains after intravascular volume and blood pressure are achieved. Similarly, intravenous corticosteroids are suggested in septic shock to help replace intrinsic loss of cortisol, but only when blood pressure remains unresponsive to volume.[27] Other supportive therapies in the treatment of severe sepsis include blood product administration to maintain hemoglobin levels between 7 and 9 g/dl, targeted tidal volume (6 ml/kg) when mechanically ventilated with plateau pressure less than 30 cm H_2O, utilization of sedation and analgesic protocols when needed, and avoidance of neuromuscular blockers if possible. Glucose concentration is to be maintained at less than 180 mg/dl. If renal dialysis is required, intermittent hemodialysis and continuous venovenous hemofiltration are considered equivalent. Bicarbonate therapy is contraindicated for the purpose of treating hypoperfusion lactic acidemia, unless the pH is <7.15. Use of deep vein thrombosis prophylaxis, such as low-dose unfractionated heparin or low-molecular-weight heparin,

or mechanical compression prophylaxis of heparin, is contraindicated. Stress ulcer prophylaxis with H2-receptor antagonists or proton pump inhibitors is indicated. Digestive tract decontamination and selective oropharyngeal decontamination are recommended in the prevention of ventilator-acquired pneumonia.[29] It is important to discuss advance directives with the individual and family.[27] Seeking to decrease use of antibiotics in the critically ill and, thus, prevent resistance to antibiotics is an important strategy in treating infection (see What's New? Procalcitonin Levels). Recent research suggests that monitoring serial procalcitonin (PCT) levels, a precursor hormone to calcitonin, may be used to shorten antibiotic use in the treatment of respiratory tract infections.[30] PCT, normally not discernible on assay, when elevated may indicate specific proinflammatory response during bacterial infection. PCT levels should not be used as an indicator to start antibiotics, but if monitored sequentially at the start of empiric antibiotics and then dropping to low levels, discontinuation may be clinically indicated.[30,31]

MULTIPLE ORGAN DYSFUNCTION SYNDROME

Multiple organ dysfunction syndrome (MODS) is the progressive dysfunction of two or more organ systems resulting from an uncontrolled inflammatory response to a severe illness or injury. The organ dysfunction can progress to organ failure and death. MODS occurs during severe sepsis. In 2001, an international consensus conference developed a set of definitions for sepsis and related disorders (see Table 48-1), and a predisposition-infection-response-organ (PIRO) dysfunction staging system was proposed as a template for staging sepsis (Table 48-2). MODS is the end stage of a variety of injuries that terminate in severe, generalized inflammatory response.

MODS was first recognized as a distinct clinical syndrome in the mid-1970s[32,33] when advances in resuscitation and support technologies allowed many individuals to survive life-threatening illness or trauma only to die of complications of their disease. Today MODS is a leading cause of mortality in surgical intensive care units (ICUs). Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems. Moreover, mortality has not improved much over the past 15 to 20 years.[34,35]

Although sepsis and septic shock are the most common causes, MODS can be initiated by any severe injury or disease process that activates a massive systemic inflammatory response by the host. Documented clinical infection is not necessary for its development. Other common triggers are severe trauma, major surgery, burns, circulatory shock, acute pancreatitis, acute renal failure, ARDS, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, DIC, and necrotic tissue (Box 48-1). MODS is the major cause of death following septic shock, trauma, burn injuries, and ARDS. People at greatest risk for developing

TABLE 48-2 PREDISPOSITION-INFECTION-RESPONSE-ORGAN (PIRO) DYSFUNCTION SYSTEM FOR STAGING SEPSIS

DOMAIN	PRESENT	FUTURE	RATIONALE
Predisposition	Premorbid illness with reduced probability of short term survival Cultural or religious beliefs Age Sex	Genetic polymorphisms in components of inflammatory response Enhanced understanding of specific interactions between pathogens and host diseases	Premorbid factors affect the potential attributable morbidity and mortality of an acute insult Deleterious consequences of insult heavily dependent on genetic predisposition (future)
Infection	Culture and sensitivity of infecting pathogens Detection of disease amenable to source control	Assay of microbial products Gene transcription profiles	Specific therapies directed against inciting insult require demonstration of characterization of that insult
Response	SIRS Other signs of sepsis Shock C-reactive protein	Nonspecific markers of activated inflammation or impaired host responsiveness Detection of specific target of therapy	Mortality risk and potential to respond to therapy vary with nonspecific measures of disease severity Specific mediator-targeted therapy is predicated on presence and activity of mediator
Organ dysfunction	Organ dysfunction as number of organs or composite score	Dynamic measures of cellular response to insult—apoptosis, cytopathic hypoxemia, cell stress	Response to preemptive therapy not possible if damage already present Therapies targeting the injurious cellular process require that it be present

MODS are older adults and persons with significant tissue injury or pre-existing disease.[18]

The PIRO system (see Table 48-2), a clinically useful sepsis staging system, stratifies individuals with disease by baseline risk of adverse outcomes and potential to respond to therapy.[18]

PATHOPHYSIOLOGY. In **primary MODS** the organ injury is directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or trauma, thermal injury, soft tissue necrosis, or invasive infection.[36] This decreased perfusion is local (in the injured organs themselves) and generalized. The generalized hypoperfusion in primary MODS usually cannot be detected clinically. As a result of the insult, a stress response is initiated and stress hormones—in particular, catecholamines—are released. The inflammatory and stress responses are not as evident as they are in secondary MODS. In primary MODS during the inflammatory response, presumably neutrophils and macrophages are "primed" by cytokines.[36] Any second insult, such as additional tissue injury, infection, or organ ischemia, may then activate the primed cells to produce an exaggerated response of secondary MODS[36,37] (Figure 48-8).

The progressive organ dysfunction of **secondary MODS** is the result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury. Often the second insult is mild but produces an immense disproportionate response because of the previous priming of leukocytes. The interaction of injured organs then leads to a self-perpetuating inflammation.

Secondary MODS is initiated by the delayed postinjury insult as primed macrophages release a barrage of mediators, particularly the cytokines TNF and IL-1. These mediators damage the endothelium throughout the body. If a gram-negative bacterial infection is present, endotoxin released from the bacteria also causes severe damage to endothelial cells. Normal endothelial cells have little interaction with leukocytes, but when stimulated by TNF, IL-1, IL-6, or endotoxin, they change to a proinflammatory state and express adhesion molecules that mediate adhesion of neutrophils. The adhered neutrophils then migrate through the endothelium, aggregate in the area of damaged tissue, and amplify the inflammation.[3] The activated endothelial cells increase production and release of nitric oxide (endothelium), a potent vasodilator that is considered an important factor in the blood flow changes and loss of vascular tone noted in systemic inflammation.[38] The injured endothelium also becomes much more permeable, allowing fluid and protein to leak into the interstitial spaces. An important function of normal endothelium is anticoagulation. When damaged, the endothelium loses much of its ability to prevent blood clotting, allowing microvascular thrombi to develop.

The postinjury insult also activates the neuroendocrine system, resulting in a second, more extensive stress response. The normal function of the stress response is to maintain basal and stress-related homeostasis[39]; however, homeostasis cannot be maintained in MODS. In fact, the endocrine response becomes excessive and injurious. There is an early increase in the levels of circulating catecholamines that contributes to many of the clinical manifestations of MODS, such as tachycardia, hypermetabolism, and increased oxygen consumption. Cortisol, glucagon, insulin, human growth hormone, ADH (which may become depleted), and endorphin levels also are increased. Many of these hormones contribute to the extreme catabolic state of MODS, and endorphins, which are vasodilators, decrease SVR. The sympathetic nervous system, to compensate for complications resulting from the injury (e.g., fluid loss, hypotension), also is stimulated. The stimulation persists throughout the period of critical illness.[39] The stress response can be amplified by a number of factors, including pain, anxiety, psychosis, and hyperthermia. (The stress response is discussed in detail in Chapter 11.)

Because of endothelial cell dysfunction and the release of mediators, four major plasma cascades are activated: complement, kallikrein-kinin, coagulation, and fibrinolytic.[40] Complement components, particularly the anaphylatoxins C3a and C5a, cause vasodilation by stimulating release of histamine from mast cells. They also have strong chemotactic properties. C5a, especially, causes adhesion and the activation and degranulation of neutrophils. Complement is thought to be a powerful trigger for the exaggerated inflammatory response. Activation of the kinin system results in the production of bradykinin, a very potent vasodilator known to decrease SVR. Coagulation mechanisms also are activated, and because tissue injury and endothelial dysfunction are extensive, microvascular

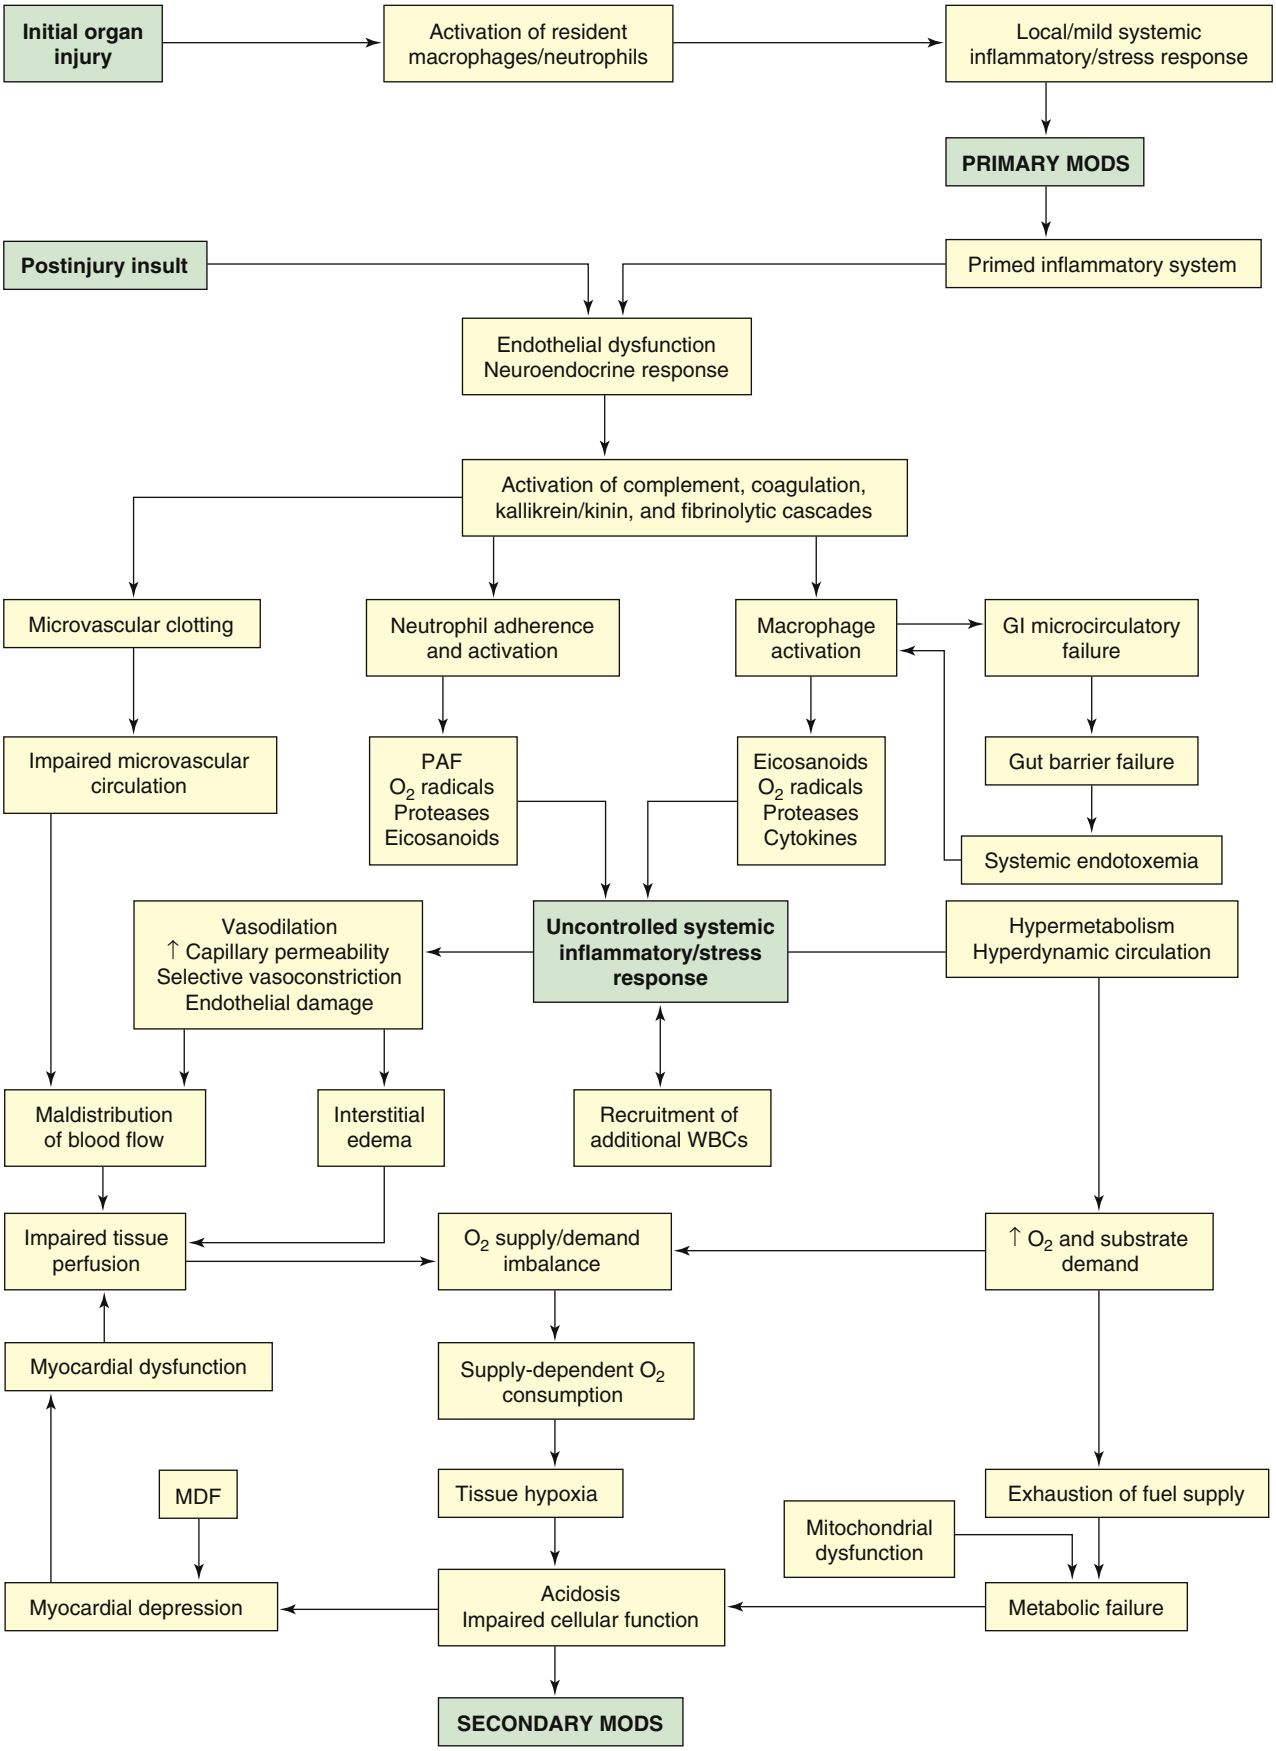

FIGURE 48-8 Pathogenesis of Multiple Organ Dysfunction Syndrome. *GI,* Gastrointestinal; *MDF,* myocardial depressant factor; *MODS,* multiple organ dysfunction syndrome; *PAF,* platelet-activating factor; *WBCs,* white blood cells.

thrombosis occurs throughout the body, resulting in impaired microvascular circulation and organ ischemia. Concurrently, fibrinolytic mechanisms are activated. The tendency toward clotting, however, is greater, resulting in a net procoagulant state that can lead to the development of DIC. The overall effect of the activation of the plasma cascades is a hyperinflammatory and hypercoagulant state that contributes to vasodilation, vasopermeability, cardiovascular instability, endothelial dysfunction, and clotting abnormalities.[41]

Once cytokines and other mediators have been released and the plasma enzyme cascades have been activated, a massive systemic inflammatory response develops. It involves several types of inflammatory cells, particularly neutrophils, macrophages, and mast cells. These cells, having been primed by their response to the initial organ injury, now pour large amounts of chemical mediators into tissues and into the systemic circulation. Neutrophils have tremendous inflammatory potential. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS.[42] When neutrophils adhere to the endothelium, they undergo a "respiratory burst" (oxidative burst) and release oxygen-free radicals. The respiratory burst occurs as the activated neutrophil experiences a sudden increase in oxidative metabolism, producing large quantities of highly toxic oxygen-free radicals. These reactive oxygen species (ROS) cause oxidative stress. The primary ROS produced are superoxide, hydrogen peroxide (H_2O_2), hydroxyl radical (OH^-), and singlet oxygen (O). Oxygen-free radicals are extremely damaging to vascular endothelium and tissue cells, attacking deoxyribonucleic acid (DNA), cross-linking membrane structures, and inducing membrane peroxidation—reactions that disorganize cell membranes and lead to tissue necrosis[3,24] (also see Chapter 2).

Other important mediators released by neutrophils are proteases, particularly collagenase and elastase. Proteases directly damage endothelium and neighboring cells, resulting in increased capillary permeability and organ damage. When activated, neutrophils also release platelet-activating factor (PAF), a mediator that damages endothelium, stimulates clot formation, and activates increasing numbers of phagocytes. Finally, neutrophils release arachidonic acid metabolites (eicosanoids) as a result of lipid peroxidation of their cell membranes. Of the arachidonic acid metabolites (prostaglandins, thromboxanes, leukotrienes), two are particularly important in the pathogenesis of organ hypoperfusion: prostacyclin (PGI_2) and thromboxane A_2 (TXA_2). TXA_2 is a powerful vasoconstrictor, and PGI_2 is a potent vasodilator. When released in varying amounts in different organ beds, they are largely responsible for the maldistribution of blood flow characteristic of MODS. In total, neutrophils produce at least 50 to 60 toxins.[43,44] Collectively, products released by neutrophils cause endothelial dysfunction, systemic vasodilation, selective vasoconstriction (vasoconstriction of certain organ beds or parts of organ beds), increased vascular permeability, and microvascular coagulation.

Macrophages, present in most tissues, are activated by endotoxin, complement, and monocyte chemotactic substances.[45] Macrophages share a key role in the development of the unregulated inflammation of secondary MODS with the neutrophils. Like neutrophils, they produce oxygen-free radicals, proteases, cytokines, nitric oxide, and arachidonic acid metabolites. It has been reported that excessive or prolonged stimulation of macrophages leads to the overproduction of cytokines and nitric oxide that initiate the cycle of harmful effects in MODS.[3,24,45] TNF and IL-1, which share many of the same functions and act synergistically, are the major cytokines that mediate inflammation.[45,46] TNF has potent metabolic effects, including fever, anorexia, hyperglycemia, hypermetabolism, and weight loss. It activates neutrophils, damages endothelial cells, and potentiates hypotension and shock. IL-1 also has metabolic effects, inducing fever, hypermetabolism, and muscle wasting. Normally, TNF activates cytokines, the coagulation system, fibrinolysis, and neutrophils. With the exception of neutrophil activation, IL-1 causes similar activation in individuals with cancer.[47] In the pathogenesis of MODS, the cytokines are linked to all cellular, hemodynamic, and metabolic alterations.

The gastrointestinal mucosa is particularly vulnerable to inflammatory mediators released by macrophages and neutrophils. Under normal circumstances the gut mucosa serves as a barrier to prevent bacteria from the gastrointestinal tract from entering the systemic circulation. Damage to the mucosa results in microcirculatory failure of the gut and consequent loss of the gut barrier function. The loss of intestinal barrier function leads to the systemic spread of bacteria and/or endotoxin from the gut (systemic endotoxemia). This phenomenon is called *translocation of bacteria.* The idea that the gut acts as a reservoir of bacteria and endotoxin that can initiate or perpetuate the development of MODS is known as the **gut hypothesis.** The gut hypothesis provides a possible explanation for the fact that an infectious focus is not always found in individuals with MODS. Although this hypothesis has been substantiated by animal studies and has much support, the evidence from human studies is inconclusive.[48,49]

The numerous inflammatory processes operating in MODS cause maldistribution of blood flow and hypermetabolism. **Maldistribution of blood flow** refers to the uneven distribution of flow to various organs and between the large vessels and capillary beds of the body. It is caused by generalized vasodilation, increased capillary permeability, selective vasoconstriction, endothelial dysfunction, and impaired microvascular circulation. It is a major factor in the pathophysiology of MODS.[40] The alterations in blood flow—which can occur at the cellular, organ, or regional level—lead to impaired tissue perfusion and a decreased supply of oxygen to the cells. The organs most severely affected by hypoperfusion are the lungs, splanchnic bed, liver, and kidneys. Despite supernormal systemic blood flow, oxygen delivery to the tissues decreases. Several factors contribute to the problem. First, blood is shunted past selected regional capillary beds. Shunting, caused by loss of autoregulation in some organs, may be an early indicator of progression of sepsis into MODS.[50] This occurs because inflammatory mediators, particularly TXA_2, override the normal vascular control mechanisms to cause selective vasoconstriction and because injured endothelial cells are unable to respond to normal vasodilator mediators. Second, interstitial edema, resulting from microvascular permeability, contributes to decreased oxygen

delivery to cells by increasing the distance oxygen must travel to reach the cells. Third, capillary obstruction occurs because of the formation of microvascular thrombi and the aggregation of leukocytes.[3,24,45]

Hypermetabolism, with accompanying alterations in carbohydrate, fat, and lipid metabolism, is initially a compensatory measure to meet the body's increased demands for energy. Eventually, however, hypermetabolism becomes detrimental, placing enormous demands on the heart. Hypermetabolism is the result of: (1) the neuroendocrine response to stress with the release of catecholamines and cortisol, and (2) the action of TNF and IL-1. With increased metabolism the calorie requirements are markedly increased,[34] and the cardiac output increases 1.5 to 2 times normal.[51] The alterations in metabolism affect all aspects of substrate use. Most important is the catabolism of protein, primarily of skeletal muscle and visceral organs. The extreme catabolism of protein can rapidly deplete lean body mass. Hyperglycemia occurs as gluconeogenesis by the liver increases and glucose use by the cells decreases. Fatty acids are mobilized from adipose tissue. The net result of the hypermetabolism is depletion of oxygen and fuel supplies.

Myocardial depression also accompanies MODS. The cause remains unclear, but possible explanations are the effects of myocardial depressant factor (MDF), TNF, and IL-1 on cardiac contractility; alterations in α-adrenergic receptors in the heart; and hypoxia of the myocardium.[52,53]

The decreased oxygen delivery to the cells (resulting from the maldistribution of blood flow) and the increased oxygen needs of the cells (resulting from hypermetabolism) combine to create an imbalance in oxygen supply and demand. This imbalance is critical in the pathogenesis of MODS because it results in a pathologic condition known as **supply-dependent oxygen consumption.** Ordinarily the amount of oxygen consumed by the cells depends only on the needs of the cells because there is an adequate reserve of oxygen that can be delivered if required. In MODS, however, the reserve has been exhausted and the amount of oxygen consumed becomes dependent on the amount the circulation is able to deliver. Because the amount is inadequate in MODS, the tissues become hypoxic. Compounding the hypoxic damage to cells is a phenomenon called *reperfusion injury* (see Chapter 2). Much of the organ damage in MODS occurs with the reestablishment of blood flow after a period of ischemia. During the ischemic episode, energy stores and ATP are depleted and the enzyme *xanthine dehydrogenase* is converted to *xanthine oxidase.* With reperfusion of the ischemic tissue, oxygen-free radicals are formed from oxygen by the action of xanthine oxidase, and they attack the already damaged tissues. Consequently, although reperfusion is necessary to restore oxygen supply to ischemic organs, it can increase the extent of injury. Therefore, because of supply-dependent oxygen consumption and reperfusion injury, tissues become increasingly hypoxic. The result is cellular acidosis, impaired cellular function, and ultimately multiple organ failure.

CLINICAL MANIFESTATIONS. In MODS the organs that show clinical manifestations of failure are not always the organs involved as part of the initial injury, and there is usually a lag time between the initial insult and the development of systemic organ failure. The development of primary MODS is difficult to monitor, but there is a well-established general pattern in the clinical development of secondary MODS.[36,54] Following the inciting event and aggressive resuscitation of the individual for approximately 24 hours, the individual develops low-grade fever, tachycardia, tachypnea, dyspnea, altered mental status, and a general hyperdynamic and hypermetabolic state (Box 48-2). Following this, the lungs begin to fail and ARDS may appear within 24 to 72 hours (see discussion of ARDS, Chapter 35). Between days 7 and 10, the hypermetabolic and hyperdynamic state intensifies; bacteremia with enteric organisms is common; and signs of hepatic, intestinal, and renal failure develop. During days 14 to 21, the renal failure and liver failure become more severe. Hematologic failure and myocardial failure are usually later manifestations. Encephalopathy, characterized by mental status changes ranging from confusion to deep coma, may occur at any time. This sequence can evolve rapidly, with death occurring between 14 and 21 days later, or it can evolve over weeks. Individuals can recover from either the slowly or the rapidly evolving course.

The clinical manifestations of failure of individual organs in MODS are caused by inflammatory mediator damage, tissue hypoxia, and hypermetabolism. Respiratory failure progresses early to ARDS and is characterized by tachypnea, pulmonary edema with crackles and diminished breath sounds, use of accessory muscles, and hypoxemia. Liver failure, although early in its development, is not clinically detectable until the later stages of MODS, when jaundice, abdominal distention, liver tenderness, muscle wasting, and hepatic encephalopathy appear. All aspects of metabolism, substance detoxification, and immune response are impaired. Albumin and clotting factor synthesis decreases, protein wastes accumulate, and liver tissue macrophages (Kupffer cells) no longer function effectively.

The gastrointestinal system is very sensitive to ischemic and inflammatory injury. Clinical manifestations of bowel involvement are hemorrhage, ileus, stress ulcers, malabsorption, diarrhea or constipation, vomiting, anorexia, abdominal pain, and pancreatitis. Intolerance to enteral feeding may develop. Adding to damage caused by injury to the bowel is bacterial translocation into the bloodstream resulting from the loss of the gut barrier function. The overwhelmed liver is unable to clear the bacteria from the systemic circulation. Thus, regardless of whether infection or some other injury was the precipitating cause of MODS, once intestinal bacteria enter the systemic circulation, it is likely that sepsis will be a problem. Renal failure develops at about the same time and is marked by progressive oliguria, azotemia, and edema. If renal shutdown is severe, anuria, hyperkalemia, and metabolic acidosis occur.

The first manifestations of cardiac failure are similar to those of septic shock: tachycardia, bounding pulse, increased cardiac output, fall in SVR, hypotension, warm skin, and supraventricular dysrhythmias. In the terminal stages, profound hypotension and ventricular dysrhythmias may develop. Changes in central nervous system function may be noted. Ischemia and inflammation are responsible for the changes, which include apprehension, confusion, disorientation, restlessness, agitation, headache, decreased cognitive ability and memory, and decreased level of consciousness. When ischemia is severe, seizures and coma can occur.

BOX 48-2 CLINICAL MANIFESTATIONS OF ORGAN DYSFUNCTION

Pulmonary
- Acute respiratory distress syndrome (ARDS) pattern of respiratory failure (dyspnea, patchy infiltrates, refractory hypoxemia, respiratory acidosis, abnormal O_2 indices)
- Pulmonary hypertension

Gastrointestinal
- Abdominal distention and ascites
- Intolerance to enteral feedings
- Paralytic ileus
- Upper and lower gastrointestinal bleeding (guaiac-positive stools)
- Diarrhea
- Ischemic colitis
- Mucosal ulceration
- Decreased bowel sounds
- Bacterial overgrowth in stool

Liver
- Increased serum bilirubin level (hyperbilirubinemia)
- Increased liver enzyme levels (serum aspartate transaminase [SAST], serum alanine aminotransferase [SALT], lactic dehydrogenase [LDH], alkaline phosphatase)
- Increased serum ammonia level
- Decreased serum transferrin level
- Jaundice
- Hepatomegaly

Gallbladder
- Right upper quadrant tenderness or pain
- Abdominal distention
- Unexplained fever
- Decreased bowel sounds

Metabolic/Nutritional
- Decreased lean body mass
- Muscle wasting
- Severe weight loss
- Negative nitrogen balance
- Hyperglycemia
- Hypertriglyceridemia
- Increased serum lactate levels
- Decreased serum albumin, serum transferrin, prealbumin, retinol-binding protein

Renal
- Increased serum creatinine level and blood urea nitrogen
- Oliguria, anuria, or polyuria consistent with prerenal azotemia or acute tubular necrosis
- Urinary indices consistent with prerenal azotemia or acute tubular necrosis

Cardiovascular
Hyperdynamic
- Decreased pulmonary capillary wedge pressure
- Decreased systemic vascular resistance
- Decreased right atrial pressure
- Decreased left ventricular stroke work index
- Increased oxygen consumption
- Increased cardiac output, cardiac index, heart rate

Hypodynamic
- Increased systemic vascular resistance
- Increased right atrial pressure
- Increased left ventricular stroke work index
- Decreased oxygen delivery and consumption
- Decreased cardiac output and cardiac index

Central Nervous System
- Lethargy
- Altered level of consciousness
- Fever
- Hepatic encephalopathy

Coagulation and Hematologic
- Thrombocytopenia
- Disseminated intravascular coagulation

Immune
- Infection
- Decreased lymphocyte count
- Anergy

Modified from Thelan LA et al: *Critical care nursing: diagnosis and management,* ed 6, St Louis, 2010, Mosby.

EVALUATION AND TREATMENT. Because there is no specific therapy for MODS, early detection or prevention is extremely important so that supportive measures are initiated instantly.[34] Frequent assessment of the clinical status of individuals at known risk is essential. Unfortunately, there is no way to determine with certainty when an organ is failing. Indicators of organ dysfunction are presented in Table 48-1.

Several systems for scoring severity of illness also have been developed. Commonly used systems are the **Acute Physiology and Chronic Health Evaluation II and III (APACHE II and APACHE III),** the logistic organ dysfunction score (LODS), the sequential organ failure assessment (SOFA), the MODS score, and the PIRO staging system.[55] Once organ failure develops, monitoring of laboratory values and hemodynamic parameters is necessary to assess the degree of clinical impairment.

The therapeutic management of MODS consists of prevention and support. Prevention of the syndrome is essential! First, if possible, the initial source of inflammation must be eliminated or controlled. Next, a second insult must be avoided. It is paramount to remove any potential site of infection by débriding necrotic tissue, draining abscesses, reducing the numbers of invasive procedures performed, and removing hematomas. Nosocomial infections from contaminated lines and catheters are of concern and must be prevented. Nosocomial infection rates of 15% to 25% have been reported in critically ill individuals.[56] Early reduction of long-bone fractures and surgical repair of injured tissues are also important preventive measures.

The goals of therapy are to control infection, provide adequate tissue oxygenation, restore intravascular volume, and support the function of individual organs.[26] After the initial

injury has been aggressively treated and sources of infection have been removed, antibiotics generally are administered. The choice of agents is based on the individual's disease process, but the regimen is usually a combination of antibiotics that covers both gram-negative and gram-positive organisms.

Because oxygen is not stored in the tissues, it must be continuously delivered. Maintaining an arterial oxygen saturation of 88% to 92% is recommended,[26] and hemoglobin levels should be kept greater than 9 g/dl.[26] Mixed venous oxygen saturation greater than or equal to 70% is recommended. Blood transfusions may be necessary to ensure an adequate hemoglobin level. To deliver oxygen to the organs in the face of profound systemic vasodilation, fluid volume must be restored. Therefore, aggressive fluid therapy is initiated early. Usually large volumes of isotonic crystalloid solutions are administered, although colloids (often albumin) also may be added to maintain adequate preload and circulation volume.[26]

Finally, support for individual organ systems must be provided. Respiratory failure is treated with mechanical ventilation with low tidal volumes, high oxygen concentrations, and positive end-expiratory pressures (PEEP).[57] To provide adequate nutrition and metabolic support, the failing gastrointestinal system is supported with enteral feedings. It is now well recognized that enteral feedings help preserve gut microbial barrier function, and thus are preferred to parenteral feedings.[58] However, if the individual is unable to tolerate the amount of enteral feeding required to meet the enormous metabolic demands, hyperalimentation may be added. Ideally the feeding formula is carefully calculated to meet the individual's nutritional requirements. Tight glucose level control (80 to 110 mg/dl) is recommended.[59] Once renal failure is established, dialysis or continuous hemofiltration may be required to maintain fluid and electrolyte balance. To support the failing cardiovascular system, inotropic drugs, such as low-dose dopamine and dobutamine, or vasopressors, such as norepinephrine, may be required to maximize cardiac contractility and maintain cardiac output. Although steroids have anti-inflammatory effects, their use is controversial because they have been shown to be effective in adults with septic shock. Obtaining an adrenocorticotropic hormone (ACTH) level is not recommended. Deep vein thrombosis prophylaxis is also important.[6]

Scientific knowledge gained about MODS and inflammatory mediators has led to many investigational therapies. Novel molecular approaches targeting a variety of interdependent mediators of MODS are being investigated.[47]

BURNS

Major thermal injury is a source of massive tissue injury and destruction that has wide-reaching effects on virtually all organ systems. **Burn** is a generic term used to describe cutaneous injury resulting from thermal, chemical, or electrical environmental causes. In addition to cutaneous injury, burns are often associated with smoke inhalation injury or other traumatic injuries that aggravate the local and systemic problems of burns. Pulmonary injury, both primary and secondary, is common and often necessitates ventilator support. The use of tracheostomy also has been examined and is controversial.[60,61] This model of multisystem injury provides an opportunity to examine the interaction of shock, inflammation, and immunocompromise in a clinical setting.

Epidemiology and Etiology

The annual number of burns and fire-related injuries that occur in the United States is now estimated to be about 450,000.[62] Deaths consequent to these injuries have decreased more than 50%—from 9000 in 1971[63] to 4000 in 2005.[62] This remarkable progress is the result of several factors, including ongoing research in burn physiology and burn care,[64] an increased national focus on fire safety and burn prevention, the establishment of regional burn centers, the use of smoke detectors, regulation of consumer product safety, and the implementation of occupational safety mandates. A decrease in hospitalization reflects a shift to outpatient care and improved prehospital and emergency treatment, but burn assessment and delivery of care can be improved[65] to reduce medical transport and treatment costs. International interest in telemedicine has increased over the past decade.[66,67] These advances in care are changing emphasis from survival to outcomes in burn survivors.[68,69]

The causes of burn injury may be **thermal** or **nonthermal,** such as chemical, electrical, or radioactive. Thermal burns may result from thermal contact, flame, or scald. Adherent materials (e.g., asphalt, tar, or plastic) may likewise produce a serious contact burn. Chemical injuries are a result of contact with substances that are directly toxic to skin or the lining of the respiratory or alimentary tract. Such chemicals are often acid, alkali, or organic agents, termed **vesicants,** that cause blistering of the epithelial surfaces. Electrical burns may be the result of the conduction of electrical current through the body with heating of tissue or flash over the body surface associated with an electrical discharge. Quality of life can be affected but, by self-reports, may exceed normal population averages with proper intervention.[70]

Burn Wound Depth

The classification of **burn wound depth** is usually based on the physical appearance and the symptoms associated with the affected skin. The definitive diagnosis is determined by the histologic depth of tissue necrosis. Such evaluation, unfortunately, necessitates a skin biopsy. Because of the invasive nature of biopsy, clinical depth assessment is used and the ultimate fate of the wound determines final diagnosis. Recent advances in laser Doppler technology have resulted in extensive exploration of a noninvasive means for burn wound depth assessment.[71-83]

First-degree burns are a **partial-thickness injury** involving only the epidermis without injury to the underlying dermal or subcutaneous tissue (Table 48-3). The skin maintains water vapor and bacterial barrier functions. Many sunburns are first-degree injuries caused by exposure of skin to ultraviolet radiation from the sun. Initially there is local pain and erythema, but no blisters appear until after about 24 hours. An extensive first-degree burn may cause systemic responses such as chills, headache, localized edema, and nausea or vomiting. No treatment of extensive first-degree burns is required unless the person is

TABLE 48-3 DEPTH OF BURN INJURY

		SECOND DEGREE		THIRD DEGREE
CHARACTERISTIC	FIRST DEGREE	SUPERFICIAL PARTIAL THICKNESS	DEEP PARTIAL THICKNESS	FULL THICKNESS
Morphology	Destruction of epidermis only	Destruction of epidermis and some dermis	Destruction of epidermis and dermis, leaving only skin appendages	Destruction of epidermis, dermis, and underlying subcutaneous tissue
Skin function	Intact	Absent	Absent	Absent
Tactile and pain sensors	Intact	Intact	Intact but diminished	Absent
Blisters	Present only after first 24 hr	Present within minutes, thin walled and fluid filled	May appear as fluid-filled blisters; often is layer of flat, dehydrated "tissue paper" that lifts off in sheets	Blisters rare; usually is a layer of flat, dehydrated "tissue paper" that lifts off easily
Appearance of wound after initial debridement	Skin peels at 24-48 hr, normal or slightly red underneath	Red to pale ivory, moist surface	Mottled with areas of waxy white, dry surface	White, cherry red, or black; may contain visible thrombosed veins; dry, hard leathery surface
Healing time	3-5 days	21-28 days	30 days to many months	Will not heal; may close from edges as secondary healing if wound is small
Scarring	None	May be present; low incidence influenced by genetic predisposition	Highest incidence because of slow healing rate promoting scar tissue development; also influenced by genetic predisposition	Skin graft; scarring minimized by early excision and grafting; influenced by genetic predisposition

elderly or an infant, in which case severe nausea and vomiting may lead to inadequate fluid intake and dehydration. Therapy consists of intravenous hydration until the nausea and vomiting subside 24 to 72 hours after burn injury. Comfort measures for previously healthy children or adults with extensive first-degree burns consist of aspirin for adults or acetaminophen for children every 4 hours in age-appropriate doses and frequent application of a water-soluble lotion. First-degree burns heal in 3 to 5 days without scarring.

Second-degree burns describe two categories of burn depth with markedly different characteristics. Both of these are partial-thickness injuries, but they evoke vastly different responses. The hallmark of **superficial partial-thickness injury** is the appearance of thin-walled, fluid-filled blisters that develop within just a few minutes after injury. Another dominant characteristic of superficial injury is pain. As blisters break or are removed, nerve endings are exposed to air (Figure 48-9). Tactile and pain sensors remain intact throughout healing, with each wound care procedure causing substantial pain. Wounds heal in 3 to 4 weeks if the individual is adequately nourished and no complications develop (Figure 48-10). Scar formation is unusual with this injury. The amount of scarring that develops is a genetically determined trait and is not predictable during the early course of treatment.

Deep partial-thickness burns involve the entire dermis, sparing skin appendages such as hair follicles and sweat glands (see Table 48-3). The burn often looks waxy white and is surrounded by margins of superficial partial-thickness injury. The injury is often clinically indistinguishable from a full-thickness injury (Figure 48-11), but by 7 to 10 days after burn injury, skin buds and hair will appear from hair follicles, indicating that skin appendages remain. These wounds take weeks to heal,

FIGURE 48-9 Superficial Partial-Thickness Injury. Scald injury following débridement of overlying blister and nonadherent epithelium. (Courtesy Intermountain Burn Center, University of Utah.)

and current therapy consists of surgical removal of the burn wound (excision) followed by application of the person's own unburned skin from another body area (autograft). Wounds that heal slowly produce more scar tissue and continue to be a potential source of infection until closed. In the presence of relative surgical contraindications, such as cardiopulmonary failure, deep partial-thickness wounds are not surgically treated but are allowed to heal primarily. The fate of partial-thickness burns can be affected by treatment, such as topical antibiotics, or by the condition of biologic membranes.[84] The ultimate healing of deep partial-thickness burns commonly results in hypertrophic scarring with poor functional and cosmetic results.

Third-degree burns, or **full-thickness injuries,** involve destruction of the entire epidermis, dermis, and often the underlying subcutaneous tissue (see Table 48-3). On occasion, all

FIGURE 48-10 Axillary Burn Scar Contracture. Note the blanching of the anterior axillary fold and small ulceration, both indicating the diminished range of motion. (Courtesy Intermountain Burn Center, University of Utah.)

FIGURE 48-11 Deep Partial-Thickness Wound. Note pale appearance and minimal exudate. (Courtesy Intermountain Burn Center, University of Utah.)

underlying subcutaneous tissue is destroyed and muscle or bone may be involved. Full-thickness wounds often appear relatively innocuous when their color is white and the delineation between normal and burned skin is not accompanied by a marked color change. Elasticity of the dermis is absent, leaving the wound dry and leathery in appearance and texture (Figure 48-12). As marked edema develops, distal circulation may be compromised in areas of circumferential burns. **Escharotomies** (cutting through burned skin) are performed to release underlying pressure. Full-thickness burns are painless because all nerve endings have been destroyed by the injury.

The extent of the **total body surface area (TBSA)** burn is estimated using either the "rule of nines" (Figure 48-13) or the Lund and Browder chart (Figure 48-14). Areas of partial-thickness and full-thickness injury are marked on the diagram in Figure 48-14. First-degree burns are not included in the TBSA estimate. The surface area of the palm, including palmar finger surface, averages 1% of the body surface area over a wide range of ages; thus it can be used to estimate burn areas of irregular size and shape.[85]

Severity of burn injury is a combination of many factors, including age, medical history, extent and depth of injury, and body area involved. The American Burn Association has defined criteria to assist healthcare professionals in identifying individuals who require care at a specialized burn center (Box 48-3). The multidisciplinary burn center is recommended for those

persons who are at high risk for morbidity, mortality, or permanent functional loss.

PATHOPHYSIOLOGY AND CLINICAL MANIFESTATIONS. Burn injury results in dramatic changes in many physiologic functions of the body within the first few hours after the event. The effect of burn depends on two factors: first, the extent of body surface involved and, second, the depth of cutaneous injury. Body surface burn extent is described by the percentage of TBSA injured. Burns exceeding 20% of TBSA in most adults are considered to be major burn injuries and are associated with massive evaporative water losses and flux of large amounts of fluid and electrolytes in the tissues, manifested as generalized edema and circulatory hypovolemia. Depth of cutaneous injury has been categorized in many ways but always depends on the severity of injury of epidermal and dermal elements of the skin and whether the alteration is a permanent or reversible injury.

With a major burn injury, a systemic pathophysiology ensues that requires therapeutic intervention to sustain life. The immediate (acute) physiologic consequences of a major burn injury

BOX 48-3 BURN UNIT REFERRAL CRITERIA

A burn unit may treat adults or children or both.

Burn injuries that should be referred to a burn unit include the following:

1. Partial-thickness burns greater than 10% total body surface area (TBSA)
2. Burns that involve the face, hands, feet, genitalia, perineum, or major joints
3. Third-degree burns in any age group
4. Electrical burns, including lightning injury
5. Chemical burns
6. Inhalation injury
7. Burn injury in individuals with pre-existing medical disorders that could complicate management, prolong recovery, or affect mortality
8. Any patients with burns and concomitant trauma (such as fractures) in which the burn injury poses the greatest risk of morbidity or mortality. In such cases, if the trauma poses the greater immediate risk, the patient's condition may be initially stabilized in a trauma center before being transferred to a burn center; physician judgment will be necessary in such situations and should be in concert with the regional medical control plan and triage protocols.
9. Burned children in hospitals without qualified personnel or equipment for the care of children
10. Burn injury in patients who will require special social, emotional, or long-term rehabilitative intervention

From Resources for Optimal Care of the Injured Patient: "Guidelines for the Operation of Burn Centers," Chicago, IL, 2006, Committee on Trauma, American College of Surgeons.

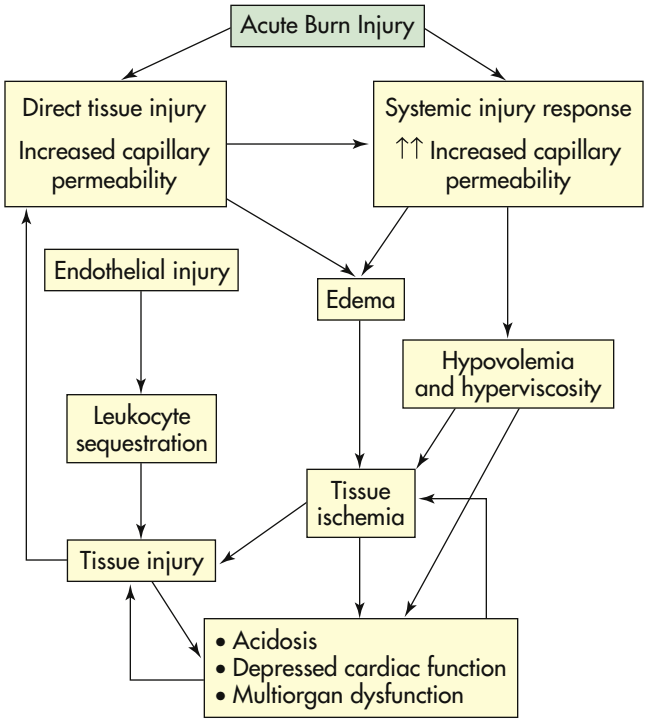

FIGURE 48-15 Immediate Cellular and Immunologic Alterations of Burn Shock.

center around the profound, life-threatening hypovolemic shock that occurs in conjunction with cellular and immunologic disruption within a few hours of injury (Figure 48-15). **Burn shock** is a phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component.

Hypovolemia associated with burn shock results from massive fluid losses from the circulating blood volume. The losses are caused by an increase in capillary permeability that persists for approximately 24 hours after burn injury. **Fluid resuscitation** is the administration of intravenous fluids, such as lactated Ringer solution, in an effort to restore the circulating blood volume during the period of increasing capillary permeability. In addition to hypovolemia, most other organ systems are affected. Cardiac contractility is diminished during the initial 24-hour resuscitation period with shunting of blood away from the liver, kidney, and gut. This is often termed the *ebb phase* of the response to trauma and can be seen with other severe injuries. Normal blood volume does not result in restoration of normal cardiac output because of a phenomenon known as *myocardial depression*. The decrease in perfusion of viscera results in a decrease in their function. This may be an explanation for decreased gut barrier function seen in thermal injury.[86] Other mechanisms include hypoxia and inflammation with histologic damage of intestinal mucosa.[87]

There also is evidence that cellular metabolism is disrupted when the burn wound is created, resulting in altered cell membrane permeability and loss of normal electrolyte homeostasis. This cellular defect may be the pathophysiologic process responsible for the genesis of burn shock. There are numerous circulating factors in burn serum that may play a role in these cellular processes. Although the cardiovascular and systemic responses are intricately interwoven into the cellular response, these responses are presented here as discrete entities for purposes of description.

Cardiovascular and Systemic Response to Burn Injury

The clinical manifestations of burn shock are the result of more than simple loss of extracellular fluid at the burn wound site. Hypovolemia and numerous local mediators in the burn wound,[88] as well as systemic signals, result in alteration of cellular function throughout the body. The restoration of normal intravascular volume with either saline solutions or colloid materials (e.g., albumin, blood, or dextrans) does not reverse changes such as increases in pulmonary vascular resistance or myocardial contractility.[89] This is reflected in cardiac output with precipitous decreases that often result in inadequate perfusion of most tissues at the capillary level, which is the hallmark of burn shock. Fluid infusion, likewise, does not return cardiac output to preburn levels.[90,91] These findings led to the postulation of a specific myocardial depressant factor (MDF).[92-94] Other causes also have been suggested, such as reactive oxygen-free radicals that attack cell membranes and other subcellular organelles as a result of first ischemia and then reperfusion of tissues during burn shock and resuscitation.[95] A third factor may be the level of nitric oxide after burn injury, which could have a direct myocardial depressant effect.[96,97] The relationship of nitric oxide and myocardial function is not yet totally clear. Gamelli and colleagues[98] found nitric oxide production to be significantly depressed in burned individuals who did not survive their injuries. They postulate that nitric oxide may scavenge reactive oxygen-free radicals and protect tissues from oxidative injury.

BOX 48-4 MAINTENANCE FLUID REPLACEMENTS AFTER MAJOR BURN INJURY*

1. *Basal fluid* replacements per day
   1500 ml/day/m^2 body surface area = 24-hour requirements
2. Evaporative water loss from burn wound
   a. Adults: 25 + % total body surface area burn ((m^2 body surface area) = ml/hr
   b. Children: 35 + % total body surface area burn (m^2 body surface area) = ml/hr
3. Total hourly maintenance fluids
   Basal fluid requirements per day ÷ 24 hours + evaporative water loss per hour = ml/hr maintenance fluids
   Example: A 70-kg adult with a 50% total body surface area burn and a body surface area of 2 m requires the following:
   - Basal = (1500 ml/day) (2 m^2 body surface area) = 3000 ml/24 hr, or 125 ml/hr
   - Evaporative = (25 + 50% total body surface burn)
   - (2 m^2 total body surface area) = (75) (2) = 150 ml/hr
   - Total maintenance fluids = 125 ml + 150 ml = 275 ml/hr

*From end of burn shock until wound closure is achieved.

Regardless of the contribution of these mechanisms, fluid resuscitation eventually results in improved outcome of the massively burned person. This resuscitation involves infusion of intravenous fluid at a rate faster than the loss of circulatory vascular volume for a period of about 24 hours from the time of burn injury, and may require up to 30 L in a major burn. Resuscitation from burn shock can be accomplished using any of a number of infusion protocols. The most frequently used protocol is the Parkland formula.[99] Lactated Ringer solution is used because it closely approximates extracellular fluid, the repository of fluid leaving the circulatory system during this phase of extensive edema formation (Table 48-4). The use of electrolyte-free fluids, such as D_5W (dextrose 5% in water), results in life-threatening hypovolemia and hyponatremia. Resuscitation with hypertonic saline has been used in some medical centers but is reserved for special circumstances; its use can result in adverse outcomes.[100]

The massive edema associated with burn shock is inevitable with fluid resuscitation, and failure to administer resuscitation fluid results in irreversible hypovolemic shock and death. The edema occurs in unburned as well as burned areas (Figure 48-16). This often leads to mechanical airway obstruction, necessitation of tracheal intubation, and increased severity of the interstitial pulmonary edema associated with inhalation injury.

The most reliable criterion for adequate resuscitation of burn shock is urine output. The individual is in hypovolemic shock and will, as a compensatory mechanism, decrease or stop urine output in an effort to preserve circulation volume. The adult receiving sufficient intravenous fluids will excrete urine amounting to 30 to 50 ml/hr; children will produce 1 ml/kg/hr. If the individual does not have adequate urine output, it often indicates inadequate fluid resuscitation. The massive amount of intravenous fluid required by burned individuals during the shock phase is often intimidating to the person unfamiliar with burns. One common concern is that massive fluid administration will result in pulmonary edema. It should be remembered that the individual is in hypovolemic shock and that fluid is lost dramatically during the resuscitation period through third spacing, exudation, and evaporation.

The endpoint of burn shock is defined as the state in which the individual is able to maintain adequate urine output for 2 hours with the intravenous fluid administration rate equal to the individual's calculated maintenance rate (Box 48-4). As burn shock ends, fluid administered remains in the circulating volume and is reflected as an increase in urine output. The mechanism whereby capillary integrity is restored is unknown but usually occurs about 24 hours after burn injury (Figure 48-17). After the individual has reached the endpoint of burn shock, the term used to describe the vascular status of the individual is **capillary seal.** In individuals with large burns, colloid-containing fluids may be given to help maintain oncotic pressure during the resuscitation phase and afterward to enhance the mobilization of interstitial fluid and diuresis.[101] Efforts to decrease burn edema and fluid resuscitation volumes can involve the use of hypertonic fluid resuscitation as well.[102]

Cellular Response to Burn Injury

In addition to capillary endothelial permeability changes resulting in vascular fluid losses, transmembrane potential changes occur in cells not directly damaged by heat. The normal potential of −90 mV decreases to nearly −70 mV, with an increase in intracellular sodium and water. Such membrane potential

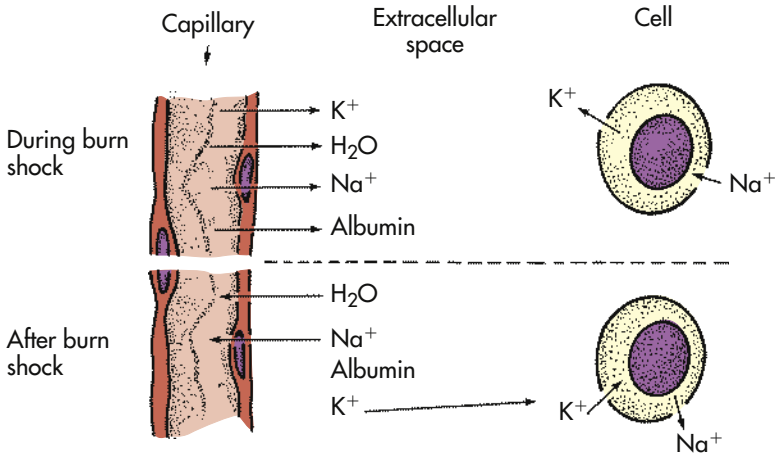

FIGURE 48-17 Direction of Fluid and Electrolyte Shifts Associated with Burn Shock. (Courtesy Intermountain Burn Center, University of Utah.)

changes may be caused by a circulating shock factor.[103] Apoptosis is central to the cellular responses to burn injury.[104] Other changes can be categorized as: (1) a metabolic response to the burn injury or (2) an immunologic response to the burn injury.

Metabolic Response. The metabolic changes after a burn injury were described in 1967 by Welt and associates as "sick cell syndrome."[105] This was considered to be a cell membrane transport defect related to an alteration in the steady-state composition characterized by high intracellular concentrations of sodium. Trunkey and colleagues[106] found a marked decrease in primate muscle extracellular water and an increase in intracellular sodium and water during hypovolemic shock. In addition, other researchers demonstrated an associated decrease in resting membrane potential, a decrease in amplitude of the action potential, and a prolongation of the repolarization and depolarization times in association with a decreased intracellular potassium concentration.[107,108] The cellular dysfunction of burn injury extends beyond the transmembrane potential disruption and the sodium-potassium pump impairment to include a loss of intracellular magnesium and phosphate[109] and elevated serum lactic acid dehydrogenase (LDH) levels.[110] Thus impairment of basic cellular function may be the underlying cause of the diminished membrane potentials. The data suggest a decrease in the efficiency of the pump. The failure of rapid intravascular volume repletion to restore membrane potential completely suggests other pathways for cellular metabolic derangement.[111]

Metabolic reactions to the stress of a major burn injury involve the response of the sympathetic nervous system and other homeostatic regulators. Catecholamines are found in elevated amounts in both the serum and urine of burned individuals. Cortisol, glucagon, and insulin levels are elevated, with a corresponding increase in gluconeogenesis, lipolysis, and proteolysis. Changes in lipid metabolism are reflected as an elevation in the levels of plasma free fatty acids (FFAs) and a decrease in the levels of plasma cholesterol and phospholipids.[112] Herndon and colleagues found that the use of propranolol, a nonselective $beta_1$- and $beta_2$-blocker, could decrease symptoms of the hypermetabolic, hypercatabolic, and osteopenic responses in pediatric patients, including a decrease in heart rate and lipolysis.[112a] Glucose and lactate kinetics are altered after burn injury. Although tissue hypoxia produces lactic acidosis, its persistence in the presence of adequate tissue perfusion suggests an increased rate of glycogenolysis.[113]

Burn injury induces a hypermetabolic state that persists until wound closure. Wilmore and colleagues[114] described the hypermetabolic state of 20 burned individuals as unrelated to ambient temperatures, with persistent elevation of core body temperatures. The metabolic rate increased with burn size in a curvilinear relationship, with oxygen consumption rarely exceeding two times basal levels. Evaporative water loss and surface cooling are not the primary stimulus for the hypermetabolic state; rather, the hypermetabolism is related to an increase and resetting of the thermal regulatory set point. A core body temperature of 38.5° C (101.3° F) is typical. A reflex arc mobilizes neural or hormonal afferent stimuli to the hypothalamus, producing a catecholamine response clinically manifested as hypermetabolism, hyperthermia, and hyperglycemia.

Evidence also exists that the burn wound itself directly mediates the response to injury at both the local and system levels. Cytokines, oxygen-free radicals, chemotactic substances, and eicosanoids contribute to the systemic inflammatory response and hypermetabolic state. The inflammatory response to the wound level is magnified into a generalized systemic inflammatory response that is often deleterious.[115-117] Vasodilation, increased capillary permeability, and edema occur to facilitate healing of the local area. The distribution of the peripheral circulation after burn injury transports heat and glucose preferentially to the wound. The energy cost of these reparative and transport processes is reflected in the increased metabolism and hyperdynamic circulation.

The extensive evaporative water loss that occurs in burn tissue is a heat-consuming process, and the energy of evaporation is provided by increased visceral heat production. The signal for the response is unknown because individuals whose wounds have been denervated continue to have a **posttraumatic hypermetabolic response.** Hypothalamic function alterations result in the elevation of human growth hormone (hGH) serum levels in the presence of hyperglycemia, a finding opposite that

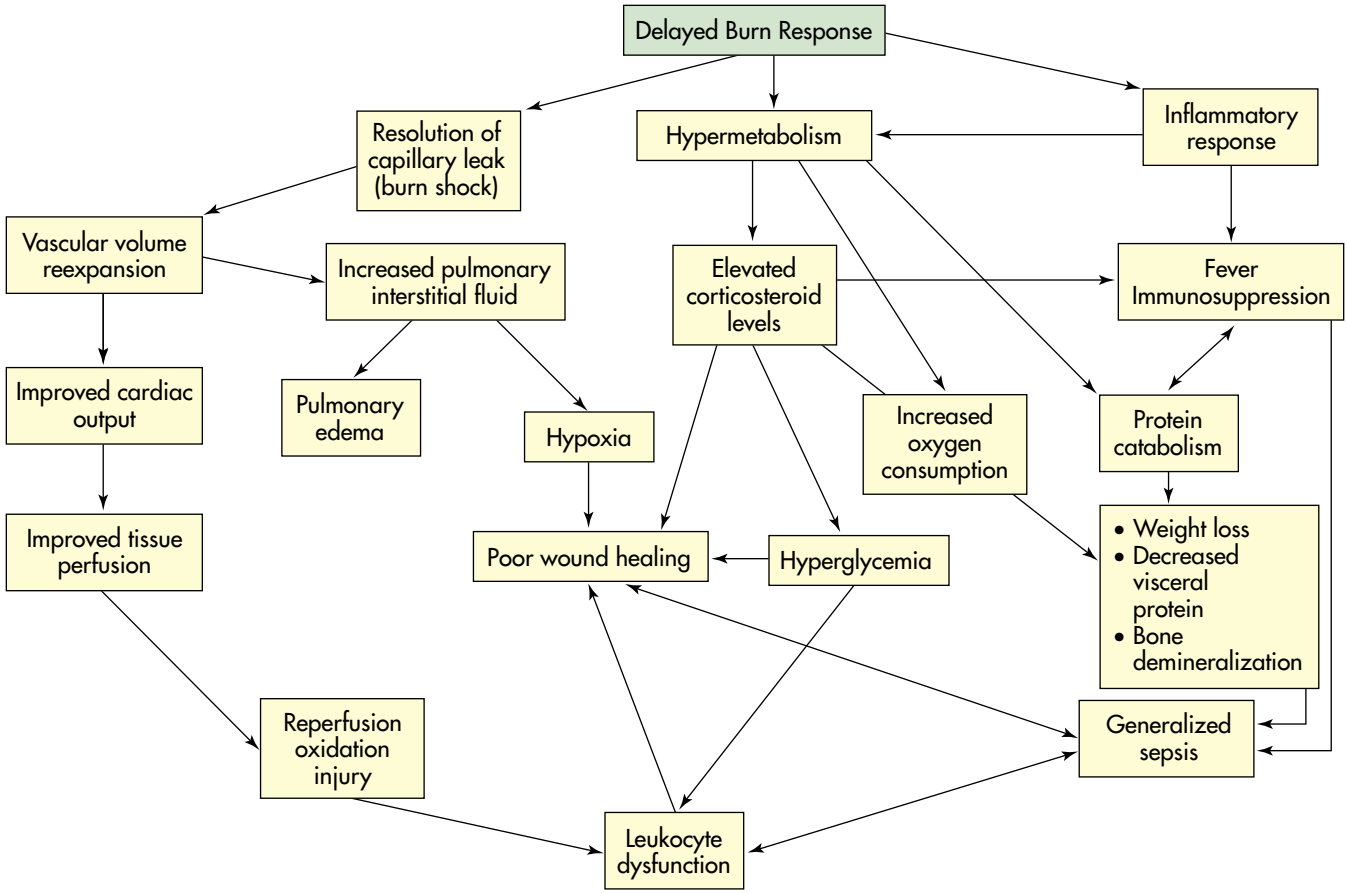

FIGURE 48-18 Physiologic Alterations in Inflammatory Burn Injury Response.

in normal states.[114] Further, the hypermetabolic rate is not decreased during rest, sleep, or warmth.

Evidence of hepatic response to burn injury is characterized by alterations in the clotting factors.[118] A hypercoagulable state develops as manifested by an elevated plasma fibrinogen concentration in the presence of shortened prothrombin time (PT) and activated partial thromboplastin time (PTT).[119]

In summary, extensive burn injury initiates the most marked alterations in body metabolism associated with any illness (Figure 48-18). Much of the work explaining this response has been conducted by Wilmore,[120,121] who reported that the persistent tachycardia, hyperpnea, hyperpyrexia, and marked body wasting seen in burn injury reflect heightened metabolic activity and accelerated body catabolism. The development of decreased bone density can last long after discharge from the hospital.[122] These system alterations occur as a result of the cutaneous inflammatory process and are thought to facilitate wound repair. The neural component of this alteration is in response to a sympathetic reaction that releases catecholamines in large amounts.

Immunologic Response. The immunologic response to burn injury is immediate, prolonged, and severe. The result in individuals surviving burn shock is immunosuppression with increased susceptibility to potentially fatal systemic burn wound sepsis.

Several cytokines have been identified in the immediate postburn period. IL-1 (interkeukin-1) is detected in the serum of burned individuals. The level of IL-1 correlates inversely with burn survival; low levels may be associated with a higher mortality.[123] Fatal burn injury has often shown decreased levels of IL-2, which may result in decreased T helper 1 (Th-1) lymphocytes. Th-1 cells produce IL-2, interferon-gamma, and TNF, which help to initiate cellular immunity and immunoglobulin G (IgG) production. IL-4 is elevated after burn injuries and causes a shift in the T helper cell production from Th-1 to Th-2 lymphocytes. Th-2 cells secrete IL-4 which promotes further conversion of nonspecific Th cells to Th-2 cells. Th-2 cells also produce other cytokines and antibodies.[124] IL-6 levels increase quickly after burn injury and remain elevated for several weeks. The level of IL-6 correlates with the extent of burn injury.[125] IL-6 and platelet-activating factor (PAF) activates polymorphonuclear neutrophils (PMNs) causing infiltration of neutrophils into burned tissue and adhesion to vascular endothelial surfaces.[126,127] IL-8 levels are elevated after burn injury, with significantly greater elevations in individuals with a TBSA burn of 40% or higher. IL-8 activity may play a role in the strong and persistent activation of neutrophils noted in people with large burns.[128] Burn blister fluid contains large amounts of IL-6 and IL-8 in addition to substances such as epidermal growth factor, platelet-derived growth factor, and TGF.[129]

Macrophages, platelets, neutrophils, and vascular endothelial cells release prostaglandins and leukotrienes, which are the byproducts of arachidonic acid metabolism. These chemical

mediators cause peripheral vasodilation, pulmonary vasoconstriction, increased capillary permeability, and local tissue ischemia in the burn wound.

A host of chemicals found in burn plasma in altered concentrations also may play a role in burn shock. These include vasoactive amines (histamine, serotonin), products of complement activation (C3a, C5a), prostaglandins, kinins, endotoxin, and metabolic hormones (catecholamines, glucocorticoids). A decrease in complement components C3a and C5a in the circulation after burn injury suggests a nonspecific activation of the complement system.[130] Activation of the complement system in injured tissue results in an inflammatory response caused by release of histamine and serotonin by C3a and C5a, because histamine and serotonin alter capillary permeability and participate in the mechanism of burn shock along with kinin polypeptides and other chemical mediators. Prostaglandins function in the inflammatory process by regulating metabolism of cells of inflammation (see Chapter 7).

Burn shock can induce changes in the integrity of the intestinal wall, facilitating bacterial translocation and endotoxemia.[131] Bacterial translocation from the gut may be a mechanism of infection leading to septic shock after burn injury and other major trauma.[132] Circulating endotoxin is correlated with the development of MODS and death after major burn injury.[133]

White blood cells are also altered at this time, when their need to inhibit sepsis is vital. Natural resistance to infection in burn wounds is a function of the nonspecific immune system; that is, resistance to microorganisms that infect wounds rests almost solely on the ability of phagocytic cells (i.e., granulocytes, macrophages) to leave the bloodstream, migrate to the site of infection, and ingest and kill microorganisms.[134] Opsonins normally render bacteria susceptible to phagocytosis but the burn injury triggers a consumptive opsoninopathy. Burn serum contains an inhibitor of C3 conversion that leads to decreased opsonization and polymorphonuclear (PMN) dysfunction.[135,136]

Individuals with altered immunocompetence before burn injury are at additional risk for complications. Opportunistic infections, such as fungal sepsis, can increase a hospital stay and ICU costs.[137] Included in this group are individuals at the extremes of age and those with cardiac disease, malnutrition, immunodeficiency disease, and a history of alcohol or drug abuse.[138,139] Additional risk factors include diabetes mellitus and pulmonary or renal dysfunction.

Evaporative Water Loss

One of the major purposes of intact skin is to serve as a barrier to evaporative water loss (EWL) from the body. With major burn injury, this ability of the skin to regulate evaporative water loss is totally disrupted. In a classic 1962 study, Moncrief and Mason[140] attempted to determine the magnitude of such a loss and determined that daily evaporative water loss was in the range of 20 times normal in the early phase of injury, with gradual decreases as wound closure is achieved. Further studies indicated that insensible water loss through burned skin is not from evaporation of water from sweat glands but rather from water vapor formed within the body and lost through the skin.[141,142]

Calculation of the amount of fluid lost by evaporative water loss includes losses from all sources. Normally the skin is the major source of insensible loss (75%) and the lungs are minor sources (25%), with a total loss of only approximately 600 to 800 ml/day. This changes dramatically with burns, because not only does skin loss increase but also lung loss increases by hypermetabolism and hyperventilation, especially in an intubated individual. Total evaporative losses exceed many liters per day in an adult with large burn wounds. Replacement of the loss is mandatory to prevent volume deficit.

FIGURE 48-19 Hypertrophic Scarring. Deep partial-thickness thermal injury can result in extensive hypertrophic scarring. (Courtesy Intermountain Burn Center, University of Utah.)

EVALUATION AND TREATMENT. Burn recovery can be long and difficult, with complications often the rule rather than the exception. The goal of burn management is wound closure in a manner that promotes survival. Scar formation with contractures is often a consequence of healing in deep partial-thickness and full-thickness burns (Figure 48-19; see also Figure 48-10). Assessment of tissue viability can be difficult in complex extremity injury; pyrophosphate nuclear scanning can assist in evaluation.[143] Early intervention may have effects on tissue survival as is evident in the zone of stasis and application of cerium nitrate.[144] The advancement in survival and outcome can be as simple as using antibiotic catheters to reduce catheter-associated bloodstream infections[145] or better glycemic management during ICU treatment.[146] Advances in care systems have shown the value of advanced practice nurses in a collaborative role in the burn ICU and emergency departments.[147]

The three essential elements of survival of major burn injury are: (1) meticulous wound management, (2) adequate fluids and nutrition, and (3) early surgical excision and grafting. Current therapy for deep partial- and full-thickness burn injury includes surgical removal of the burn tissue (excision) followed by grafting of the person's unburned skin (autograft) onto the excised wound. Techniques of early wound care, such as the use of amniotic membrane,[148] may well affect the nature of burn scarring. Satisfactory wound closure with cultured epithelial autograft (Figure 48-20) has been inconsistent and costly.[149,150] Early enthusiasm for synthetic dermal replacement has been tempered by a high rate of dermal graft loss and slow epidermal engraftment.[151,152] Such advancements in skin replacement technology include sheets of acellular dermal matrix that can be used with thin, meshed autografts or cultured epithelial autografts.[153,154] This concept also is being used on the donor site; glycosaminoglycan hydrogels, and even topical gene therapy or stem-cell applications,[155-157] may supplement donor site wound

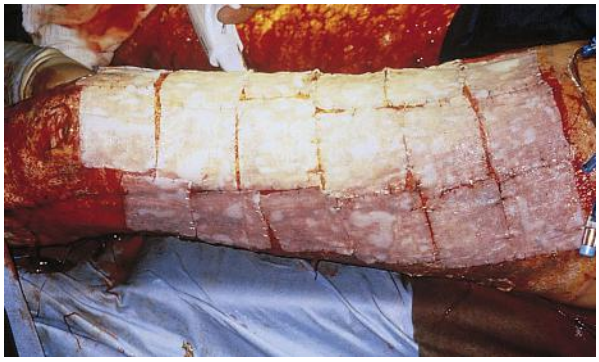

FIGURE 48-20 Application of Cultured Epithelial Autografts. The thin sheets of keratinocytes are attached to gauze backing to allow application onto the clean, excised thigh. (Courtesy Intermountain Burn Center, University of Utah.)

dressings.[158] Scar reduction or prevention is a challenging problem that is being addressed with pulsed-dye laser treatment.[159] Current research also is directed toward therapies to modulate hypermetabolic and inflammatory responses. Nutritional therapy is focused on early enteral feeding to reduce the potential of gut-mediated sepsis. Ongoing clinical trials using anabolic agents (e.g., recombinant human growth hormone) and pharmacologic agents that modulate inflammatory and endocrine mediators (e.g., ibuprofen, propranolol) show promise in the treatment of severe burn injuries.[99] Altered body image is a significant hurdle to those with facial burns. A supportive framework to aid individuals is essential to integrate them back into the community.[160] Burn pain is almost always acute and treatment strategies usually differ from strategies for chronic pain. The understanding and management of burn pain is key to recovery.[161,162] In addition to opioid-based agents, newer treatment approaches may include antianxiety agents, hypnosis, and relaxation techniques,[163] as well as virtual reality systems.[69,164]

SUMMARY REVIEW

Shock

1. Shock occurs when the cardiovascular system fails to perfuse tissue, cells, and organs adequately, causing a widespread impairment of cellular metabolism and tissue function. It is a downward physiologic spiral that, if not reversed, can lead to MODS.
2. Types of shock are cardiogenic, hypovolemic, neurogenic or vasogenic, anaphylactic, and septic.
3. The final common pathway in all types of shock is impaired cellular metabolism and cells switch from aerobic to anaerobic metabolism. Energy stores drop, and cellular mechanisms relative to membrane permeability, action potentials, and lysozyme release fail.
4. Anaerobic metabolism results in activation of the inflammatory response, decreased circulatory volume, and decreasing pH.
5. Impaired cellular metabolism results in cellular inability to use glucose because of impaired glucose delivery or impaired glucose intake, resulting in a shift of glycogenolysis, gluconeogenesis, and lipolysis for fuel generation.
6. Glycogenolysis is affected for up to 10 hours. Gluconeogenesis results in the use of proteins necessary for structure, function, repair, and replication that leads to more impaired cellular metabolism. Lipolysis is ineffective because of a lack of transport serum proteins.
7. Gluconeogenesis contributes to lactic acid, uric acid, and ammonia buildup; interstitial edema; and impairment of the immune system, as well as general muscle weakness leading to decreased respiratory function and cardiac output.
8. Cardiogenic shock results from persistent hypotension and tissue hypoperfusion caused by cardiac dysfunction in the presence of adequate intravascular volume and left ventricular filling pressure.
9. Hypovolemic shock is caused by loss of whole blood, plasma, or interstitial fluid in large amounts. The use of compensatory mechanisms may be vigorous, but tissue perfusion ultimately decreases and results in impaired cellular metabolism.
10. Neurogenic (vasogenic) shock results from massive vasodilation that results from an imbalance between parasympathetic and sympathetic stimulation of vascular smooth muscle. It causes a relative hypovolemia (even though cardiac output may be high), and results in impaired cellular metabolism.
11. Anaphylactic shock is the outcome of a widespread hypersensitivity to an allergen that triggers anaphylaxis. The inflammatory response is triggered, and a massive vasodilation with fluid shift into the interstitium follows. The relative hypovolemia leads to impaired cellular metabolism.
12. Septic shock begins with impaired cellular metabolism caused by uncontrolled septicemia. The infecting agent triggers the inflammatory and immune responses. It is part of a continuum known as SIRS. Mortality for septic shock is very high.

Multiple Organ Dysfunction Syndrome

1. MODS is the progressive dysfunction of two or more organ systems resulting from a systemic inflammatory response after a severe illness or injury. The inflammatory response can be triggered by sepsis, necrotic tissue, trauma, burns, ARDS, acute pancreatitis, major surgery, circulatory shock, DIC, acute renal failure, blood transfusion, heat stroke, liver failure, mesenteric ischemia, propofol infusion syndrome, persistent inflammatory foci, and other severe injuries.
2. Primary MODS is the immediate local or mild systemic response to the triggering event or illness. It primes the inflammatory system.

SUMMARY REVIEW—cont'd

3. Secondary MODS is the uncontrollable, excessive systemic inflammatory response that develops after a latent period and results in organ dysfunction.
4. People at greatest risk for developing MODS are older adults, those with significant tissue injury or preexisting disease, and those in whom resuscitation from the initiating illness or injury has been delayed or inadequate.
5. MODS is a leading cause of mortality in surgical intensive care units (ICUs). Mortality for individuals with MODS increases progressively from 54% with two failing organ systems to 100% with five failing organ systems.
6. Multiple organ dysfunction involves the stress response; release of complement, coagulation, and kinin proteins; changes in the vascular endothelium; and numerous inflammatory processes mediated by substances released by activated neutrophils and macrophages. The accumulation of activated neutrophils in organs is thought to play a key role in the pathogenesis of MODS, as well as macrophages.
7. The consequences of the release of inflammatory mediators in MODS are vasodilation, increased vasopermeability, and selective vasoconstriction resulting in maldistribution of blood flow; hypermetabolism; myocardial depression; and hypoxic injury to cells. Cellular hypoxia and acidosis impair cellular metabolism, leading to organ dysfunction.
8. Clinical manifestations of the development of MODS are general during the first 24 hours: low-grade fever, tachycardia, tachypnea, dyspnea, and altered mental status. Over the next several days, beginning with the lungs, individual organ systems show signs of failure.
9. Because there is no specific therapy for MODS, early detection is extremely important so that supportive measures can be initiated as soon as possible.
10. At present the therapeutic management of MODS consists of prevention or removal of triggering mechanisms and support of individual organs. Recent scientific knowledge about inflammatory mediators has led to many promising future therapies for MODS.

Burns

1. Burns are classified according to depth and extent of injury.
2. First-degree burns involve the superficial skin without loss of protective function.
3. Second-degree burns are superficial (blister formation) or superficial involving partial skin thickness with a waxy white appearance and no involvement of dermal appendages.
4. Third-degree burns involve full skin thickness and often underlying tissues. They are painless and can be life threatening as a result of hypovolemic shock and metabolic and immunologic responses.
5. The TBSA burned is estimated using either the rule of nines or the Lund and Browder chart.
6. Hypovolemia associated with burn shock is caused by increased capillary permeability with massive fluid losses from blood volume.
7. Altered cell membrane permeability and loss of electrolyte homeostasis contribute to burn shock.
8. Cardiac contractility is decreased during the first 24 hours with shunting of blood away from the liver, kidney, and gut.
9. Fluid resuscitation, such as with lactated Ringer solution, involves infusion of fluid at a rate faster than the loss of circulating volume.
10. The most reliable criterion for adequate resuscitation of burn shock is urine output.
11. Capillary seal is the term used to indicate the end of burn shock.
12. Transmembrane potentials are altered in cells not directly damaged by heat, with impairment of the sodium-potassium pump and loss of magnesium and phosphate.
13. The stress of a major burn activates the sympathetic nervous system with release of catecholamines, cortisol, glucagon, and insulin.
14. Burn injury produces a hypermetabolic state that persists until wound closure and is related to a higher thermal regulatory set point.
15. The local inflammatory response at the burn site releases cytokines, oxygen-free radicals, chemotactic factors, and eicosanoids, which lead to a systemic inflammatory response and contributes to hypermetabolism.
16. A posttraumatic hypermetabolic response is associated with increased visceral heat production.
17. Alterations in clotting factors produce a hypercoagulable state following major burns.
18. The immune response following a burn is immediate, prolonged, and severe.
19. Numerous alterations in inflammatory cytokines are evident in the immediate burn period, affecting cellular immunity, antibody production, and attraction of neutrophils and contributing to the vasodilation and increased capillary permeability associated with burn shock.
20. White blood cells are altered, and there is decreased opsonization and phagocytosis, contributing to the development of sepsis.
21. Changes in intestinal wall integrity lead to translocation of bacteria, endotoxemia, and septic shock.
22. Loss of intact skin with a major burn results in significant evaporative water loss contributing to hypovolemia.
23. Treatment of major burns involves meticulous wound management, adequate fluids and nutrition, early surgical excision and grafting, modulation of the hypermetabolic state, and pain management.

CHAPTER OUTLINE

Shock and Multiple Organ Dysfunction Syndrome, 1699
Types of Shock, 1700
Clinical Manifestations of Shock, 1700
Reperfusion and Inflammatory Injury, 1710
Evaluation and Treatment of Shock, 1710
Burns, 1715
Severity of Injury, 1716

This chapter reviews shock, multiple organ dysfunction syndrome, and burns in children. It focuses on the assessment and care of children but also notes many of the differences between these conditions in children and adults.

SHOCK AND MULTIPLE ORGAN DYSFUNCTION SYNDROME

Shock is a condition of acute and progressive circulatory dysfunction that results in inadequate delivery of oxygen and nutrients to the tissues. Shock in children most often results from hemorrhage, severe dehydration, progressive heart failure, or sepsis. It may also complicate the care of the child with congenital heart disease, pulmonary hypertension (cor pulmonale), drug toxicity, electrolyte or acid-base imbalance, dysrhythmias, or multiple organ failure.

Shock in children is present when there are signs of poor systemic perfusion, regardless of the blood pressure—shock may be present with normal, high, or low blood pressure. When the systolic blood pressure is adequate for age, but there are signs of inadequate tissue perfusion, the child is in **compensated shock.** In this child, although the systolic blood pressure may be normal, the diastolic or mean blood pressure is typically low. If systolic hypotension is associated with inadequate tissue perfusion, the child is in **hypotensive** (formerly called decompensated) **shock.**[1-3]

Shock causes tissue **ischemia** (inadequate blood flow) and **hypoxia** (inadequate oxygen delivery) that leads to acidosis and cell dysfunction. Oxygen delivery may be inadequate because arterial oxygen content or cardiac output is low, or because there are increased metabolic requirements or impaired cellular use of oxygen. Ischemia and hypoxia are primary insults to cells. Restoration of adequate blood flow and oxygen delivery may trigger the development of *reperfusion injury,* a secondary problem characterized by an exaggerated inflammatory response that may produce cellular death and organ failure.

Multiple organ dysfunction syndrome (MODS) is the simultaneous failure of at least two organs resulting from a single cause.

MODS may be either primary or secondary. Primary MODS is directly attributable to the insult and typically occurs soon (3 to 7 days) after an insult. Secondary MODS typically occurs later and may be associated with more sequential development of organ dysfunction. Risk factors for MODS include severe or prolonged shock, sepsis, trauma, cardiopulmonary arrest, congenital heart disease, and liver and bone marrow transplantation.[3-5] Children with chronic diseases have an increased risk for MODS and increased mortality.[5]

Types of Shock

Shock is categorized by type as follows:[2,3]

1. *Hypovolemic shock:* caused by inadequate intravascular volume relative to the vascular space
2. *Cardiogenic shock:* results from impairment of myocardial function
3. *Distributive shock* (including septic, anaphylactic, and neurogenic): results from inappropriate distribution of blood flow, increased capillary permeability, and myocardial dysfunction (e.g., septic or anaphylactic shock) or central nervous system injury (e.g., neurogenic or spinal shock)
4. *Obstructive shock:* caused by a mechanical obstruction to blood flow into and through the heart and great vessels (e.g., cardiac tamponade, pulmonary embolus, obstructive congenital heart lesions such as critical aortic stenosis) resulting in low cardiac output

With **hypovolemic** or **cardiogenic shock** blood flow distribution is reduced to skin, gut, and kidney to maintain blood flow to the heart and brain. With **distributive (septic, anaphylactic, and neurogenic) shock,** blood flow is unregulated throughout the skin and organ systems and vasodilation and increased capillary permeability are typically present, so a normal cardiac output is likely to be inadequate to maintain sufficient perfusion of all tissue beds. Volume administration is necessary to ensure that the intravascular volume is adequate relative to the vascular space, and vasoactive drugs are needed to support adequate cardiac output and oxygen delivery. **Neurogenic shock** is a form of hypovolemic and vasogenic (maldistributive) shock. It is caused by a loss of vasomotor tone after severe head or spinal cord injury. Massive vasodilation and loss of sympathomimetic tone result in a relative hypovolemia and hypotension. The loss of sympathetic tone prevents compensatory tachycardia.

In **obstructive shock,** low cardiac output is caused by mechanical obstruction to blood flow, such as cardiac tamponade, tension pneumothorax, critical left heart or aortic obstruction, or pulmonary embolus.[2] Obstructive shock is difficult to distinguish from cardiogenic shock because both may present with signs of low cardiac output and evidence of systemic or pulmonary venous congestion. Prompt detection and treatment are critical to survival.[2,3]

An etiologic classification of shock is helpful because it indicates the initial therapy required. However, any child with late or progressive shock is likely to demonstrate widespread cardiovascular dysfunction that may include inappropriate intravascular volume relative to the vascular space, poor myocardial function, and maldistribution of blood flow so the etiologic classification of shock is oversimplified for such children.

BOX 49-1 CLINICAL MANIFESTATIONS OF SHOCK IN NEWBORNS, INFANTS, AND CHILDREN

Signs of Shock in Infants and Children

- Change in responsiveness (initial irritability followed by lethargy)
- Tachypnea
- Mottled color, pallor (distributive shock may be associated with flushed skin)
- Tachycardia
- Cool skin, prolonged capillary refill (distributive shock may cause "flash" [instantaneous] refill)
- Diminished intensity of peripheral pulses (may also vary in intensity)
- Metabolic (lactic) acidosis (serum lactate >4 mmol/L is typically well above normal for arterial or venous blood)
- Decreased central venous oxygen saturation (more than 25% to 30% below arterial oxygen saturation)
- LATE: Hypotension, bradycardia

Nonspecific Signs of Distress in Newborns

- Jitteriness or lethargy with decreased tone
- Change in oxygen requirements
- Apnea
- Bradycardia or decreased heart rate variability
- Temperature instability, hypothermia
- Glucose instability, hypoglycemia
- Feeding intolerance (e.g., increased residual volume)

Severe shock of any kind may be followed by complications such as reperfusion injury or MODS. An etiologic classification is also incomplete for children with septic shock, because sepsis produces elements of hypovolemic and cardiogenic shock in addition to the complications of infection and maldistribution of blood flow. Thus, healthcare providers must assess and support all aspects of cardiovascular function and oxygen delivery during the treatment of any form of shock.

Clinical Manifestations of Shock

The child with inadequate cardiac output demonstrates signs of inadequate blood flow to some tissue beds and evidence of organ system dysfunction (Box 49-1). Critical parameters to evaluate when approaching the child include assessment of consciousness, breathing, and color. This initial assessment is described in the Pediatric Advanced Life Support course.[2] Through this assessment the provider determines if the child "looks good" (appears stable, in no acute distress) or "looks bad" (in need of immediate intervention).[6] More detailed assessment of organ function and acid-base status will detect evidence of inadequate organ perfusion.

The child's level of *consciousness* and *responsiveness* often provides valuable information about the severity of illness. The healthy infant should orient to faces, make eye contact, and track bright objects across a visual field. The healthy toddler is reluctant to be separated from parents or examined by strangers, and the healthy child is alert and responds to questions. By comparison, the critically ill infant or child is often extremely irritable; lethargy indicates severe deterioration in the child's level of consciousness. A decreased response to painful

stimulation is abnormal and usually indicates severe cardiorespiratory or neurologic compromise.[2,6]

The infant or child normally *breathes* without evidence of distress or increased effort, such as retractions or nasal flaring. An extremely rapid respiratory rate (tachypnea), increased depth of respirations (hyperpnea), or evidence of increased respiratory effort (e.g., retractions, grunting) may indicate the presence of heart failure or shock. The development of apnea or inadequate respiratory rate or effort may indicate deterioration and need for immediate support of airway, oxygenation, and ventilation.

If perfusion is adequate and the ambient temperature is warm, the child's *color* will be consistent over the surface of the skin, with pink lips and mucous membranes. Children who are in a cold environment, those who have undergone hypothermic surgery or a procedure in a cold room, and children in shock often demonstrate mottling (a marbled or "blotchy" appearance to the skin).[2,3,6] Pallor also may be observed when perfusion is poor (Figure 49-1). Children with sepsis occasionally demonstrate flushed, bright red skin.[2,3,6]

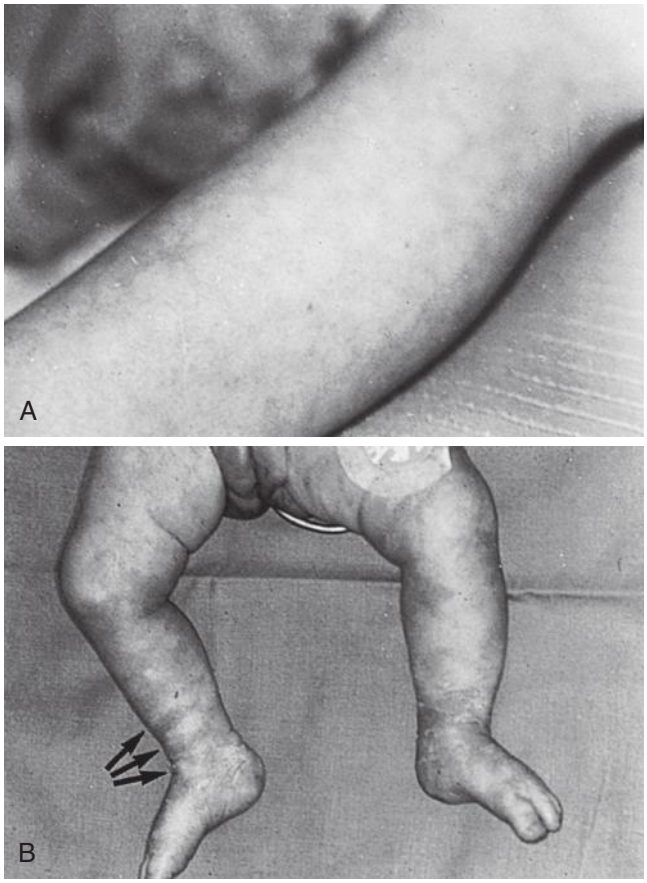

FIGURE 49-1 Mottling of Skin Caused by Poor Systemic Perfusion. **A,** Mottling of skin color often indicates inadequate tissue oxygenation; this may result from hypoxemia or poor systemic perfusion. This child developed myocardial dysfunction and signs of cardiogenic shock. **B,** Mottled skin color is often associated with other signs of compromise of skin perfusion, including delayed capillary refill. The skin over this infant's right ankle was blanched using three fingers (arrows), and the skin failed to perfuse for more than 5 seconds. This infant suffered from septic shock. (From Hazinski MF: Cardiovascular disorders. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 2, St Louis, 1992, Mosby.)

If perfusion is adequate and the ambient temperature is warm, the child's capillary refill is normally brisk (<2 seconds). A prolonged capillary refill time (>2 seconds) may indicate a compromise in systemic perfusion (see Figure 49-1, *B*) and the development of shock.[2,3,6] However, evaluation of capillary refill time is subjective and gradual changes may be difficult to detect.[7]

The child's *vital signs* must be evaluated in light of the child's clinical condition. Normal vital signs are not always appropriate in the seriously ill or injured child[6] (Box 49-2 and Table 49-1).

The child's heart rate should be appropriate for age and clinical condition. The child in shock is often tachycardic. The **tachycardia** may be primary (i.e., associated with a tachydysrhythmia) or secondary to stress (i.e., sinus tachycardia). If the heart rate is extremely rapid or if it is present in the child with decreased myocardial function, tachycardia may be the cause rather than the symptom of shock. In general, if the ventricular rate exceeds 200 to 220/min in the infant or 160 to 180/min in the child, ventricular diastolic filling time and coronary artery perfusion time are significantly reduced and stroke volume falls. As a result, cardiac output falls and signs of heart failure or shock develop. Once supraventricular or ventricular tachycardia produces signs of shock, urgent treatment is required.[8]

Bradycardia, an abnormally low heart rate, can cause a fall in cardiac output or it can be a symptom of deterioration. In young animal models, a fall in heart rate produces a commensurate fall in cardiac output.[9] The most common cause of bradycardia in young children is hypoxia.[2,10] Therefore, if the infant or child develops bradycardia with poor perfusion, the provider must immediately assess and support the child's airway, oxygenation, and ventilation, and be prepared to initiate chest compressions if the heart rate and systemic perfusion do not improve.[2,6,10]

BOX 49-2 ESTIMATING BLOOD PRESSURE IN CHILDREN 1 TO 10 YEARS OF AGE

Typical systolic BP for 1-10 years of age: The typical "normal" (i.e., median, or 50th percentile) systolic blood pressure for a child 1 to 10 years of age of normal height may be estimated by adding 90 mmHg to twice the child's age in years (90 mmHg + [2 × age in years]); this corresponds to the 50th percentile systolic blood pressure for the child's age.

Hypotensive systolic BP for 1-10 years of age: A systolic pressure less than 70 mmHg plus twice the child's age in years (<70 mmHg + [2 × age in years]) is considered hypotensive for children 1 to 10 years of age because this blood pressure corresponds to the 5th percentile systolic blood pressure for age (i.e., only 5% of normal, healthy children of average height demonstrate a systolic blood pressure lower than that number).

Hypotensive mean arterial pressure for 1-10 years of age: A mean arterial pressure less than 40 mmHg + (1.5 × age in years) is consistent with hypotension because this mean arterial pressure corresponds to the 5th percentile mean arterial pressure in children of average height.

Data from Chameides L et al, editors: Systematic approach to the seriously ill or injured child. In *Textbook of pediatric advanced life support,* Dallas, 2011, American Heart Association; Hacque IU, Zaritsky AL: *Pediatr Crit Care* 8:138–144; 2007.

TABLE 49-1 NORMAL PEDIATRIC VITAL SIGNS

AGE	HEART RATES: AWAKE HEART RATE (Per min)	HEART RATES: SLEEPING HEART RATE (Per min)	RESPIRATORY RATE* (Breaths Per min)
Newborn	100-205	90-160	
Infant (6 mo)	100-180	90-160	30-53
Toddler	98-140	80-120	27-37
Preschooler	80-120	65-100	20-28
School-age child	75-118	58-90	18-25
Adolescent	60-100	50-90	12-20

AGE	BLOOD PRESSURES: SYSTOLIC BLOOD PRESSURE (mmHg)†	DIASTOLIC BLOOD PRESSURE (mmHg)†	MEAN ARTERIAL PRESSURE (mmHg)‡	SYSTOLIC HYPOTENSION (mmHg)§
Birth (12 hr, <1000 g)	39-59	16-36	28-42¶	<40-50
Birth (12 hr, 3-kg weight)	60-76	31-45	48-57	<50
Newborn (96 hr)	67-84	35-53	45-60	<60
Infant (1-12 mo)	72-104	37-56	50-62	<70
Toddler (1-2 yr)	86-106	42-63	49-62	<70 + (2 × age in years)
Preschool (3-5 yr)	89-112	46-72	58-69	<70 + (2 × age in years)
School-age child (6-7 yr)	97-115	57-76	66-72	<70 + (2 × age in years)
Preadolescent (10-12 yr)	102-120	61-80	71-79	<90
Adolescent (12-15 yr)	110-131	64-83	73-84	<90

NOTE: Always consider patient's normal range and clinical condition. Heart and respiratory rates normally increase with fever or stress.
From Hazinski MF: Children are different. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby.
*Respiratory rates from Fleming S et al: Normal ranges of heart rate and respiratory rate in children from birth to 18 years of age: a systematic review of observational studies, *Lancet* 377:1011–1018, 2011.
†Systolic and diastolic blood pressure ranges assume 50th percentile for height for children 1 year and older, and are consistent with the Pediatric Advanced Life Support course (Chameides L et al: *Pediatric advanced life support provider manual*, Dallas, 2011, American Heart Association).
‡Mean arterial pressures (Diastolic pressure + [Difference between systolic and diastolic pressures ÷ 3]) for 1 year and older, assuming 50th percentile for height.
§Threshold for hypotension in children 1 to 10 years old from Pediatric Advanced Life Support course (Chameides L et al: *Pediatric advanced life support provider manual*, Dallas, 2011, American Heart Association).
¶Approximately equal to postconception age in weeks (may add 5 mmHg).
Blood pressure ranges from the following sources: Gemelli M et al: *Eur J Pediatr* 149:318–320, 1990; Versmold H et al: *Pediatrics* 67:107, 1981; Haque IU, Zaritsky AL: *Pediatr Crit Care* 8:138–144, 2007; National Heart, Lung and Blood Institute: *Fourth report on the diagnosis, evaluation, and treatment of high blood pressure in children and adolescents*, Bethesda, MD, 2004, National Heart, Lung and Blood Institute. Available at www.nhlbi.nih.gov/guidelines/hypertension/child.tbl.htm. Accessed July 10, 2013.

Bradycardia often indicates impending cardiovascular collapse and is the most common terminal cardiac rhythm observed in children.[2,3,6,10] The child's stroke volume may be altered by conditions affecting ventricular preload, compliance, contractility, and afterload (Table 49-2). Evaluate and optimize each of these variables in the treatment of shock (see Chapter 48).

Evaluate the child's *blood pressure* in light of age and clinical condition; note that shock may be present despite a systolic blood pressure within the normal range for age. When hypovolemic or cardiogenic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean and diastolic arterial pressures may fall. The development of systolic hypotension in the child with hypovolemic or cardiogenic shock indicates severe shock, and rapid deterioration may follow. In septic shock, by comparison, mild systolic hypotension may develop early in the clinical course. However, in all children, the development of systolic hypotension or a fall in mean arterial pressure indicates hypotensive shock, and urgent treatment is needed.[2,3,6]

The central venous pressure (CVP) is normally 0 to 5 mmHg and the pulmonary artery wedge pressure (PAWP, also called pulmonary artery occlusion pressure [PAOP]) is normally 5 to 8 mmHg or less. Inadequate CVP or PAWP may indicate hypovolemia, whereas high measurements typically result from heart failure or cardiogenic shock. Note that in the absence of tricuspid valve disease, tension pneumothorax, or influence from positive pressure ventilation, the CVP reflects the right ventricular end-diastolic pressure, whereas the PAWP should, in the absence of mitral valve disease, reflect the left ventricular end-diastolic pressure (if the catheter is appropriately placed and calibrated). The cardiac silhouette is normally less than 50% of the width of the chest on chest radiograph.

If a central venous catheter is in place, the superior vena cava (SVC) oxygen saturation is monitored to evaluate the balance of oxygen delivery versus consumption. The SVC saturation is central venous oxygen saturation ($S_{CV}O_2$) that is used as a surrogate for mixed venous oxygen saturation that would require a sampling of blood from the pulmonary artery. Normally, the

TABLE 49-2 FACTORS AFFECTING CARDIOVASCULAR PERFORMANCE IN CHILDREN

FACTOR	COMMENTS
Heart rate	Major factor affecting cardiac output in children. Normally more rapid in children than in adults. Because the *stroke volume* is smaller than in adults, the *cardiac output* of the child is more closely related to heart rate than stroke volume. *Tachycardia* is expected in the seriously ill or injured child. The most common cause of *bradycardia* in young children is hypoxia; bradycardia is an ominous sign if present in association with poor perfusion. Urgent treatment is required once bradycardia or supraventricular or ventricular tachycardia produces signs of shock.
Stroke volume	Averages 1.5 ml/kg; affected by conditions altering ventricular preload, compliance, contractility, and afterload
Ventricular end-diastolic pressure (VEDP)	Optimal pressure for children in shock is unknown. Aggressive fluid administration is linked to improved survival in children with *septic* shock.
Ventricular compliance or distensibility	Can be affected by congenital heart defects such as atrial septal defects (ASDs) and complex congenital heart defects. If compliance is low, such as in newborns and infants, volume administration may increase VEDP. Hypoplastic ventricles are often noncompliant. Hypertrophied ventricles, present in children with severe pulmonary stenosis or aortic stenosis, may become fibrotic and noncompliant. Increased compliance may be present in early septic shock.
Contractility	Contractility probably similar in normal newborns, infants, children, and adults. Newborn myocardium does have fewer contractile proteins and higher water content than adult myocardium, but the clinical significance of this is probably minimal.
Afterload	Newborn myocardium *can* adapt to mild, nonacute increases in afterload. Afterload may be increased in children with systemic vasoconstriction or pulmonary hypertension (constrictors include alveolar hypoxia, acidosis, hypothermia, and alveolar distention). Some uncorrected congenital heart defects may increase afterload. Coarctation of the aorta and aortic stenosis increase left ventricular afterload. Pulmonary stenosis increases right ventricular afterload. Afterload may be decreased in septic shock.
Oxygen delivery and consumption	Highest per kilogram body weight during the neonatal period and infancy. The young child requires a higher cardiac output and oxygen delivery per kilogram than the adult. Increased oxygen consumption occurs in critically ill newborns exposed to cold because they cannot shiver to generate heat. Other causes of increased oxygen consumption in children and infants include fever, sepsis, trauma, pain, and seizures.

VEDP, Ventricular end-diastolic pressure.

$S_{CV}O_2$ is 25% to 30% below the arterial oxygen saturation. A fall in $S_{CV}O_2$ can indicate a fall in oxygen delivery (caused by decreased arterial oxygen content or decreased cardiac output), an uncompensated rise in oxygen consumption, or both.[3]

Shock compromises renal perfusion, so urine volume decreases, typically to less than 2 ml/kg/hr in infants, less than 1 ml/kg/hr in children, and less than 0.5 ml/kg/hr in adolescents, despite adequate fluid intake. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate to greater than 4 mg/dl indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Infants have high glucose needs and low glycogen stores that may be rapidly depleted during stress. For this reason, *hypoglycemia* (glucose ≤60 mg/dl) may be observed in seriously ill or injured infants and may be associated with cardiovascular or neurologic deterioration.[2,11] *Hyperglycemia* (>150 mg/dl) may develop in critically ill or injured children as the result of a relative insulin-resistant state associated with high levels of endogenous catecholamines and hydrocortisone secretion.[3,11] Such hyperglycemia in children is often observed in the first 12 to 18 hours after initial injury or development of shock, then falls to normal levels; persistent hyperglycemia (>180 mg/dl or 10 mmol/L) has been linked with poor survival in critically ill children,[12,13] and hypo-, hyperglycemia, and glucose instability (episodes of both hypo- and hyperglycemia in same child) have been linked with development of multiple organ dysfunction.[13]

Hypovolemic Shock

Hypovolemic shock, the most common type of shock in children, is associated with a reduction in the intravascular volume relative to the vascular space. Dehydration and trauma are the most common causes of hypovolemic shock in children. A relative hypovolemia also may result from vasodilation and a redistribution of blood volume or from increased capillary permeability, such as may develop following burns or with sepsis.

When hypovolemia is mild or moderate, such as with 5% to 10% dehydration or mild hemorrhage, compensatory adrenergic vasoconstriction redistributes blood from the skin, the mesenteric (gut), and renal circulations to maintain blood flow to the heart and brain. The child with mild hypovolemic shock typically maintains systolic blood pressure with this vasoconstriction.

Hypotension is a sign of severe, decompensated hypovolemic shock and may not develop unless intravascular volume loss is rapid or severe.[2,3] Hypotension typically develops with greater than 10% isotonic or hypotonic dehydration in the infant or child (or greater than 6% to 7% dehydration in the adolescent).[11] Hypotension may not be observed in the child with trauma unless hemorrhage totals about 20% to 25% of circulating blood volume.[14,15]

Relative hypovolemia may be caused by a decrease in the intravascular volume relative to the vascular space. This may be associated with the vasodilation of sepsis, anaphylaxis, or neurogenic shock (see following text) or with β_2-adrenergic drug toxicity. A relative hypovolemia also may be caused by

increased capillary permeability with a redistribution of intravascular volume, such as with burns, anaphylaxis, or sepsis. The translocation of extravascular fluid to a location that is neither intravascular nor intracellular, as in edema, is termed **"third spacing" of fluids.**[11]

Compensatory Responses. Significant dehydration, hypovolemia, and low cardiac output stimulate adrenergic and renal compensatory mechanisms characterized by the "fight-or-flight" response. These include tachycardia and redistribution of blood from the skin, gut, and kidney to the brain and heart. Reduced renal perfusion stimulates the renin-angiotensin-aldosterone system, resulting in renal sodium and water retention. Decreased atrial stretch stimulates the secretion of antidiuretic hormone (ADH, also known as arginine vasopressin [AVP]) and produces free water retention by the kidneys.[3] These mechanisms are similar in adults and children and may help restore or maintain intravascular volume over time. Neonatal and young infant kidneys, however, are incapable of excreting concentrated urine, so these compensatory mechanisms are relatively ineffective during the first weeks of life.[11]

Compensatory mechanisms cannot be maintained indefinitely. Systemic vasoconstriction increases left ventricular afterload and myocardial oxygen consumption and may produce tissue ischemia. Prolonged tachycardia may impair subendocardial blood flow and increase myocardial oxygen consumption; both may ultimately contribute to myocardial ischemia.[3] Extreme tachypnea increases oxygen demand and reduces effective ventilation. A severe compromise in blood flow and systemic perfusion contributes to cerebral, renal, or hepatic ischemia and possible organ failure.

CLINICAL MANIFESTATIONS. The child with hypovolemic shock demonstrates signs of inadequate blood flow to some tissue beds and some evidence of organ system dysfunction (see Box 49-1). The infant or child may be irritable or lethargic. Respirations will be rapid and may be labored if shock is severe or associated with myocardial failure. The skin will be mottled, although pallor also may be observed. A prolonged capillary refill time (>2 seconds) is consistent with the development of shock.[2,3,6,16]

The child in hypovolemic shock is often tachycardic. Bradycardia often indicates impending cardiovascular collapse or cardiac arrest and is the most common terminal cardiac rhythm observed in children.[2,3,10] When hypovolemic shock is present, compensatory vasoconstriction may initially maintain the systolic blood pressure, although the mean arterial pressure may fall. The development of systolic hypotension often indicates severe shock, and rapid deterioration may follow. The CVP is less than 5 to 8 mmHg, unless heart failure or pulmonary hypertension is present.

Hypovolemic shock compromises renal perfusion so urine volume decreases despite adequate fluid intake. Liver enzymes may be elevated if hepatic perfusion is reduced. The development of metabolic acidosis and a rise in serum lactate indicate that blood flow to some tissues is inadequate to support aerobic metabolism.

Hypoglycemia (glucose ≤60 mg/dl) may be observed in seriously ill or injured infants, especially if intake has been compromised, and may be associated with cardiovascular or neurologic deterioration. *Hyperglycemia* (>150 mg/dl) may develop in critically ill or injured children.

Clinically significant dehydration is associated with weight loss (Table 49-3). Fluid intake and output records (or reports

TABLE 49-3 DEHYDRATION AND HYPOVOLEMIA

TYPE OF DEHYDRATION	CLINICAL INDICATORS
Isotonic dehydration	Fluid output exceeds intake. Loss of free water is proportional to loss of sodium, so serum sodium concentration remains normal. Fluid loss is from intravascular and extravascular compartments. Compromises peripheral perfusion when the young child has lost approximately 10% (100 ml/kg) of body weight. Compromises systemic perfusion in the adolescent with acute fluid loss equivalent to 5% to 6% of body weight. Produces hypotension (decompensated shock) when the young child has lost 15% (150 ml/kg) of body weight. Produces hypotension in the adolescent with a fluid loss equivalent to 7% to 9% of body weight because body water constitutes a smaller percentage of body weight in older children and adults than in young children.
Hypotonic/hyponatremic dehydration	Associated with a proportionately greater loss of sodium than free water; thus the serum sodium falls. Resultant acute fall in serum osmolality produces an acute extravascular fluid shift and further loss of extravascular volume. Fluid loss in hypotonic dehydration is primarily from the intravascular compartment; thus a compromise in systemic perfusion will be observed after even small quantities of fluid loss. Poor peripheral perfusion occurs in a child with a fluid loss equivalent to 5% (50 ml/kg) of body weight. Adolescents with hyponatremic dehydration may demonstrate a compromise in peripheral perfusion with a fluid loss equivalent to approximately 3% of body weight. Hypotension often is observed when fluid loss is equal to approximately 10% (100 ml/kg) of body weight. Hypotension in an adolescent is observed when the fluid loss equals approximately 5% to 6% of body weight.
Hypertonic/hypernatremic dehydration	Free water deficit is proportionately greater than the deficit of sodium, so serum sodium concentration rises, increasing serum osmolality and producing an intravascular shift of free water. For this reason the child with hypernatremic dehydration is likely to maintain intravascular volume and systemic perfusion until relatively large quantities of fluid are lost. Compromise in systemic perfusion is not likely to be observed in the *child* with hypernatremic dehydration until *severe* dehydration is present with a fluid loss equivalent to 10% of body weight (or 5% to 6% of body weight in the adolescent). Hypotension may not be observed until the fluid loss approximates 15% or more of body weight (7% to 9% or more of body weight in the adolescent). Hypotension in the child with hypertonic/hypernatremic dehydration indicates a substantial fluid deficit. However, the deficit must be replaced carefully to correct shock and avoid rapid lowering of serum sodium concentrations.

Data in part from Roberts KE: *Pediatr Rev* 22:380–386, 2001; Roberts KE: Fluid, electrolyte and endocrine problems. In Hazinski MF, editor: *Nursing care of the critically ill child*, ed 3, St Louis, 2013, Mosby.

TABLE 49-4 SEVERITY OF (ISOTONIC) DEHYDRATION BASED ON CLINICAL EXAM*

CLINICAL PARAMETERS	MILD	MODERATE	SEVERE
Body weight loss			
Infant	5% (50 ml/kg)	10% (100 ml/kg)	15% (150 ml/kg)
Adolescent	3% (30 ml/kg)	5%-6% (50-60 ml/kg)	7%-9% (70-90 ml/kg)
General appearance	Alert, restless, thirsty	Lethargic, postural dizziness	Limp, coma, cold and cyanotic extremities
Radial pulse	Full	Thready, weak, rapid	Feeble, not palpable
Respiration	Normal	Deep	Deep, rapid
Skin elasticity	Pinch retracts immediately	Pinch retracts slowly	Pinch retracts very slowly (>2 seconds)
Eyes	Normal	Sunken	Very sunken
Tears	Present	Diminished	Absent
Mucous membranes	Moist	Dry	Very dry (parched)
Urine output	Normal	↓	↓ or absent
Capillary refill time	<2 seconds	>2 seconds	Prolonged
Heart rate	Varies with age	Varies with age	Varies with age
Blood pressure	Normal	Normal	Reduced

Modified from Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby.

*The interpretation of the assessments must be appropriately modified for age and type of dehydration (hypotonic or hypertonic).

TABLE 49-5 ESTIMATION OF PEDIATRIC CIRCULATING BLOOD VOLUME

AGE OF CHILD	BLOOD VOLUME (ml/kg body weight)
Newborn	80-85
Infant	75-80
Child	70-75
Adolescent	65-70

From Hazinski MF: Children are different. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby.

from parents or primary caretakers) reveal a history of inadequate fluid intake or excessive fluid losses. The child with significant dehydration demonstrates dry mucous membranes, a sunken fontanel (in infants), and poor skin turgor[11] (Table 49-4). Moderate isotonic dehydration produces signs of peripheral circulatory compromise, and severe isotonic dehydration will produce hypotension. The blood urea nitrogen (BUN) and urine specific gravity are usually elevated. The serum sodium concentration and osmolality are affected by the type and severity of dehydration present.

Hemorrhage is another potential cause of hypovolemic shock. To appreciate the significance of any blood lost or drawn for laboratory analysis, the total blood loss should be considered as a percentage of the child's circulating blood volume (Table 49-5).

Tachycardia, peripheral vasoconstriction, and altered level of consciousness may be the only early evidence of hemorrhage in the child with trauma (Table 49-6). Acute blood loss (hemorrhage) may not compromise a child's peripheral perfusion until an estimated 25% to 30% of intravascular volume is lost (i.e., an acute intravascular or blood loss of 16 to 24 ml/kg).[14-16] Once hypotension develops, cardiovascular collapse is imminent and immediate, rapid intravascular volume expansion is required and surgical intervention may be needed.

Redistribution of blood volume associated with systemic vasodilation, high capillary pressure or transudative fluid losses, or capillary leak may produce a relative hypovolemia and signs of poor systemic perfusion in the absence of evidence of absolute volume loss. For example, children with end-stage hepatic failure may demonstrate a relative hypovolemia associated with ascites and hepatorenal syndrome. Children demonstrate increased capillary permeability and loss of intravascular volume immediately after a burn. The septic child also may demonstrate systemic edema associated with capillary leak and intravascular volume loss. In these children some evidence of extravascular fluid movement (ascites, systemic edema, or fluid loss to dressings over burns) is usually observed.

Signs of neurogenic shock in the child with a recent, severe spinal cord injury include warm skin and hypotension with a low diastolic blood pressure. Signs of poor systemic perfusion also are observed (see Clinical Manifestations of Shock, previously), although loss of sympathetic nervous system tone prevents the typical tachycardic response.

Cardiogenic Shock

Cardiogenic shock is present when impaired myocardial function compromises cardiac output. This form of shock is observed:

1. Following cardiovascular surgery or with inflammatory disease of the heart, such as cardiomyopathy and myocarditis
2. With drug toxicity or severe electrolyte or acid-base imbalances
3. As a complication of any form of shock and early in septic shock

Compensatory Responses. In the early stages of cardiogenic shock, adrenergic compensatory mechanisms produce tachycardia, peripheral vasoconstriction, and constriction of the splanchnic arteries to divert blood flow from the skin, gut, and kidneys to maintain flow to the heart and brain.[2,3,16] These compensatory mechanisms may be sufficient to maintain the

TABLE 49-6 CLASSIFICATION OF PEDIATRIC HEMORRHAGIC SHOCK IN TRAUMA PATIENTS BASED ON CLINICAL EVALUATION

SYSTEM	MILD HEMORRHAGE, COMPENSATED SHOCK, SIMPLE HYPOVOLEMIA (<30%)	MODERATE HEMORRHAGE, DECOMPENSATED SHOCK, MARKED HYPOVOLEMIA (30%-45%)	SEVERE HEMORRHAGE, CARDIOPULMONARY FAILURE, PROFOUND HYPOVOLEMIA (>45%)
Cardiovascular	Tachycardia Weak peripheral pulses, strong central pulses Low to normal blood pressure (systolic BP >70 mmHg + [2 × (age in years)]) Mild acidosis	Moderate tachycardia Thready peripheral pulses, weak central pulses Frank hypotension (systolic BP <70 mmHg + [2 × (age in years)]) Moderate acidosis	Severe tachycardia Absent peripheral pulses, thready central pulses Profound hypotension (systolic BP <50 mmHg) Severe acidosis
Respiratory	Mild tachypnea	Moderate tachypnea	Severe tachypnea
Central nervous system	Irritable, confused	Agitated or lethargic	Obtunded, comatose
Skin	Cool extremities, mottling Poor capillary refill (72 sec)	Cool extremities, pallor Delayed capillary refill (72 sec)	Cool extremities, cyanosis Prolonged (>5 sec) capillary refill
Kidneys	Mild oliguria, increased specific gravity	Marked oliguria, increased blood urea nitrogen (BUN)	Anuria

From Soud T, Pieper P, Hazinski MF: Pediatric trauma. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 2, St Louis, 1992, Mosby.

child's systolic blood pressure and effective coronary artery and cerebral blood flow. However, tachycardia and systemic arterial constriction increase myocardial oxygen consumption. In addition, reduction in gut and kidney blood flow may produce hepatic, mesenteric, or renal ischemia or failure. Decreased renal perfusion stimulates the renin-angiotensin-aldosterone system, as described for hypovolemic shock.

If the mean arterial pressure or pulse pressure falls, stimulation of the baroreceptors in the carotid sinuses and aortic arch is reduced. This reduced baroreceptor activity removes inhibition from the vasomotor center in the medulla, resulting in increased adrenergic stimulation.[3] If myocardial dysfunction progresses, cardiac output and systemic blood pressure ultimately fall. Myocardial ischemia then exacerbates myocardial dysfunction, and multisystem organ failure may result from persistent or severe organ ischemia.

CLINICAL MANIFESTATIONS. The child with cardiogenic shock demonstrates signs of inadequate systemic perfusion despite adequate intravascular volume or even relative hypervolemia. This form of shock is generally associated with low cardiac output. The child's extremities are cool to touch (will cool peripherally to proximally), with delayed capillary refill despite a warm, ambient temperature.[2,6,16] The skin may be mottled (see Figure 49-1).

Evidence of an adequate or high central venous pressure, including hepatomegaly and periorbital edema, is typically present in uncomplicated cardiogenic shock, particularly if right ventricular failure is involved. Evidence of pulmonary edema may be noted on a chest radiograph or clinical assessment (including signs of respiratory distress, reduced lung compliance during hand ventilation, or frothy pink sputum suctioned from the endotracheal tube) if left ventricular failure is present. The cardiac silhouette is usually enlarged on the chest radiograph, unless concurrent hypovolemia is present. If myocardial function is severely compromised, peripheral pulses may be diminished in intensity (dampened) or they may vary in intensity (pulsus alternans).

A low cardiac output may be documented by invasive or noninvasive devices. If a pulmonary artery catheter is in place, the cardiac output may be calculated through a thermodilution technique or continuous monitoring of the mixed venous oxygen saturation.

Signs of low cardiac output and cardiogenic shock may be identical to signs of cardiac tamponade. Although some classic signs of tamponade, including muffled heart tones or pulsus paradoxus may be observed, these signs may be difficult to appreciate if cardiac output and blood pressure are severely compromised. Therefore, if cardiogenic shock is suspected in a child after cardiovascular surgery or in any child at risk for the development of pericardial effusion, tamponade should be ruled out through an echocardiogram.

Septic Shock

Sepsis and its complications result from activation of biochemical and physiologic cascades that lead to the formation or activation of cytokines and other mediators that produce vasodilation, increased capillary permeability, maldistribution of blood flow, and cardiovascular dysfunction.[3] Sepsis and its complications may result in organ system dysfunction and are leading causes of death in noncoronary intensive care units. An estimated 42,000 pediatric cases of sepsis are reported annually in the United States and result in approximately 4400 deaths per year.[17]

Much information about the pathophysiology and clinical signs of sepsis has been extrapolated from adult studies and adult animal models of sepsis. Some information gleaned from adult experience is applicable to children, whereas other information is not. More research is needed to better understand pediatric sepsis and septic shock.

Watson's 2003 hospital data from seven states[17] still provides the most detailed information regarding causes of pediatric sepsis in the United States. The most common sites of infection from these data were primary bloodstream (25%) and

respiratory tract (37%) infections;[17] about half of children with sepsis had an underlying disease and more than one fifth were low–birth-weight neonates.[17,18]

Many bloodstream and respiratory infections may be prevented with proper handwashing by healthcare providers before and after contact with children, appropriate sterile and aseptic technique during catheter insertion and tubing changes, and use of protocols to reduce central venous catheter infections and ventilator-associated pneumonias.[19,20] More pediatric data are needed to develop evidence-based recommendations to reduce hospital-acquired infections and sepsis.

The microorganisms that cause sepsis vary according to age, immune function, and location (e.g., in the hospital versus in the community).[21] Approximately 40% of all hospital-acquired infections in adults and children are linked to gram-negative infections; 40% to gram-positive infections; and 20% to viruses, fungi, or rickettsial microorganisms.[18] Prevention of hospital-acquired infections can substantially reduce the risk of sepsis and its complications.[19,20] Clinicians must be aware of the common pathogens in various populations.

Factors associated with risk for the development of sepsis include extremes of age (infants, young children and older adults)[3,17]; invasive catheters, surgical incisions, or wounds or burns; immunocompromise; and long-term antibiotic therapy.[17,18] Many of these risk factors are present in seriously ill or injured children and children with a chronic disease.

It is now clear that genetic variations among children and among invading microorganisms can alter the outcome of infections, sepsis, and septic shock.[21] Genetic variation in any of several genes that affect host responses to invading microorganisms can influence outcomes of infections.[22] Certainly, infectious diseases, such as meningococcal disease, can vary widely in their invasiveness and in the severity of effects on the host.[23] It is anticipated that genetic information will ultimately influence identification of a child's susceptibility to infection and sepsis, risk modification, early detection of sepsis, tailoring of therapy, and prognostication.[22]

Both proinflammatory and anti-inflammatory cytokines serve essential protective functions in fighting infection and modulating the immune response. Sepsis is caused by the effects of the invading microorganism and its toxins, but most effects that contribute to shock result from a disruption in the balance between *proinflammatory* mediators (including tumor necrosis factor-alpha [TNF-α], interleukin [IL]-1, IL-6, and IL-8; platelet-activating factor; arachidonic acid metabolites; nitric oxide; and many kinins) and *anti-inflammatory* mediators (IL-4, IL-10, IL-11, and IL-13; transforming growth factor-beta; colony-stimulating factors; soluble tumor necrosis factor receptor; IL-1 receptor antagonist; and activated protein C).[3] Extremely high levels of proinflammatory mediators, such as TNF, nitric oxide, and platelet-activating factor can become destructive, even after the triggering microorganism is eradicated.[3,21]

High proinflammatory cytokine levels have been implicated in the development of sepsis-induced disseminated intravascular coagulation, pulmonary injury, and microcirculatory disruptions, such as are observed in burns, severe trauma, shock reperfusion syndromes, and MODS.[21] Tumor necrosis factor levels have been directly related to mortality in newborns and children with meningitis and sepsis,[24] and interleukin-8 levels have been shown to be reliable predictors of pediatric sepsis mortality.[22]

Increased nitric oxide concentrations are thought to contribute to vasodilation, hypotension, and decreased myocardial function that develop during adult sepsis. In comparison, infants with sepsis often demonstrate pulmonary vasoconstriction resulting from shock-induced acidosis and hypoxia, and may benefit from administration of inhaled nitric oxide or other vasodilators.[25]

During sepsis, endotoxin stimulates the endothelium to become a secretory organ. The endothelium changes from the normal profibrinolytic and anticoagulant state to an antifibrinolytic and precoagulant one.[25] This change can lead to the development of microthrombin in some areas of the microcirculation, further contributing to maldistribution of blood flow. Mediators (e.g., activated protein C) that regulate coagulation pathways have been implicated in the sepsis process.[25-27] Activated protein C also regulates inflammation and activated protein C deficiency is a marker for severe sepsis in all ages.[27] Although administration of activated protein C improved survival in adults with severe sepsis,[28] it has not been shown to improve outcome in children and may produce excessive bleeding complications.[25]

There is clear interaction among catecholamines, adrenoreceptors, and glucocorticoids. Endogenous glucocorticoids have an anti-inflammatory effect (they decrease activation of proinflammatory mediators), and they modulate vasomotor tone by enhancing cardiovascular and vasomotor response to catecholamines.[29]

Critically ill children may have adrenal insufficiency (caused by adrenal hemorrhage, decreased renal perfusion, inhibition of corticosteroid production by TNF, or actual adrenal disease) or a relative adrenal insufficiency, with inadequate adrenal stress response or decreased response to circulating glucocorticoids.[30,31] When sepsis is present and the child fails to respond to initial fluid therapy and vasoactive support, providers should rule out adrenal insufficiency and consider hydrocortisone administration, especially if risk of adrenal insufficiency is present.[32]

CLINICAL MANIFESTATIONS. Sepsis and its complications produce a cascade of physiologic and biochemical changes. The clinical progression of sepsis in children has been described and defined by a consensus panel of international physicians[4] (Box 49-3).

Systemic inflammatory response syndrome (SIRS) represents a nonspecific response to a variety of insults, including trauma, burns, pancreatitis, or infection. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline: change in temperature, specifically fever (greater than 38.5° C [101.3° F]) or hypothermia (less than 36° C [96.8° F]), change in heart rate (tachypnea or, in infants, bradycardia), change in respiratory rate (or need for mechanical ventilation), or change in white blood cell (WBC) count (including leukocytes, leukopenia, or an increase in the percentage of immature or band forms of WBCs).[4] These clinical signs must be interpreted in light of the child's baseline function.

BOX 49-3 INTERNATIONAL CONSENSUS DEFINITIONS OF SYSTEMIC INFLAMMATORY RESPONSE SYNDROME, SEPSIS, SEVERE SEPSIS, AND SEPTIC SHOCK IN CHILDREN

Systemic Inflammatory Response Syndrome (SIRS)

The presence of at least two of the following four large bulleted criteria, one of which must be abnormal temperature or leukocyte count:

- ALTERATION IN TEMPERATURE: Core body temperature of >38.5° or <36°C
- ALTERATION IN HEART RATE (characterized by any of the three open bullets, below):
  - Tachycardia in the absence of external stimulus, chronic drugs, or painful stimuli, defined as follows:
    - Newborn to 1 year: HR >180/min
    - 2-5 years: >140/min
    - 6-12 years: >130/min
    - 13 to <18 years: >110/min
  - Otherwise unexplained persistent elevation over a 0.5 to 4-hour time period
  - For children younger than 1 yr: bradycardia, in the absence of external vagal stimulus, β-blocker drugs, or congenital heart disease, defined by one of the three dashes below:
    - Newborn to 1 month: <100/min
    - 1 month to 1 year: <90/min
    - Otherwise unexplained persistent depression over a 30-minute time period
- ALTERATION IN RESPIRATORY RATE (characterized by either of the open bullets, below):
  - Mean respiratory rate >95th percentile normal for age, defined as follows:
    - Newborn to 1 week: >50/min
    - 1 week to 1 month: >40/min
    - 1 month to 1 year: >34/min
    - 2-5 years: >22/min
    - 6-12 years: >18/min
    - 13 to <18 years: >14/min
  - Mechanical ventilation for an acute process not related to underlying neuromuscular disease or the receipt of general anesthesia
- ALTERATION IN WHITE BLOOD CELL COUNT:
  - Leukocyte count elevated or depressed for age (not secondary to chemotherapy-induced leukopenia) or >10% immature neutrophils

Infection (one of the following)

- A suspected or proven (by positive culture, tissue stain, or polymerase chain reaction test) infection caused by any pathogen
- A clinical syndrome associated with a high probability of infection

Note: Evidence of infection includes positive findings on clinical examination, imaging, or laboratory tests (e.g., white blood cells in a normally sterile body fluid, perforated viscus, chest radiograph consistent with pneumonia, petechial or purpuric rash, purpura fulminans)

Sepsis

- SIRS in the presence of or as a result of suspected or proven infection

Severe Sepsis

- Sepsis plus one of the following:
  - Cardiovascular organ dysfunction
  - Acute respiratory distress syndrome
  - Two or more other organ dysfunctions (organ dysfunctions are defined in Box 49-4)

Septic Shock

- Sepsis and cardiovascular organ dysfunction as defined in Box 49-4

From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, St Louis, 2013, Mosby; Modified from Goldstein B et al: *Pediatr Crit Care Med* 6:2–8, 2005.

Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed in conjunction with suspected infection. Positive blood or other cultures are not necessary for the diagnosis, but suspicion of infection is required.[4] For example, if the child with trauma develops a high fever or pulmonary congestion several days after injury, it is highly likely that an infection is present.

Severe sepsis is present when the child demonstrates evidence of sepsis (SIRS with suspected infection) and signs of cardiovascular or pulmonary dysfunction, or if the child has sepsis and evidence of two or more other organ dysfunctions (Box 49-4).[4] Altered organ perfusion is signaled by signs of organ system dysfunction. The dysfunctional organ system should be separate from the site of suspected infection and not explained by effects of drug therapy or other acute effects.[4] This important distinction will enable separation of signs of severe sepsis from signs of simple pneumonia and associated respiratory failure.

Septic shock is heralded in the child with sepsis by the development of cardiovascular dysfunction. This may be characterized by hypotension despite adequate fluid resuscitation or by the need for vasopressors to maintain blood pressure.[4] Because children tend to develop hypotension only late in the course of any shock, septic shock should be identified when the child develops more subtle signs of poor perfusion despite adequate fluid resuscitation. When the child with sepsis does develop hypotension plus signs of poor perfusion, hypotensive/decompensated septic shock is present, and mortality may be as high as 30%.[33]

Kissoon, Orr, and Carcillo[34] have proposed simplified diagnostic criteria for pediatric septic shock. They note that fever, tachycardia, and vasodilation are signs of inflammation. They propose that if the child with this triad of inflammatory signs also develops altered level of consciousness, the diagnosis of septic shock should be considered. Carcillo[25,34] has distilled the international consensus definitions of septic shock to include suspected infection with hypo- or hyperthermia and clinical signs of inadequate perfusion. Carcillo defines signs of inadequate perfusion as including any one of the following: decreased level of conscious or change in mental status; prolonged (>2 seconds) capillary refill; abnormal pulses (either diminished or bounding with wide pulse pressure); mottled, cool extremities; or decreased urine output. Carcillo also notes that hypotension is not required for the diagnosis but, if present, is confirmatory.[25,34]

Children with septic shock may have a high, normal, or low cardiac output. Unlike adults, who typically present with

BOX 49-4 CRITERIA FOR ORGAN DYSFUNCTION IN CHILDREN WITH SEVERE SEPSIS OR SEPTIC SHOCK

Cardiovascular

Despite administration of isotonic intravenous fluid boluses of more than 40 ml/kg in 1 hour, is described by the characteristics in one or more of the three bullets below:

- Decrease in blood pressure (BP) (hypotension) to <5th percentile for age, estimated for children 1-10 years of age as follows:
  - Mean arterial pressure: <40 mmHg + (1.5 × age in years)
  - Systolic BP <70 mmHg + (2 × age in years)
- Need for vasoactive drug to maintain BP in normal range (dopamine >5 mcg/kg/min; or dobutamine, epinephrine, or norepinephrine at any dose)
- Two of the following:
  - Unexplained metabolic acidosis: base deficit more severe than –5 mEq/L
  - Increased arterial lactate >2 times upper limit of normal
  - Oliguria: urine output <0.5 ml/kg/hr
  - Prolonged capillary refill: >5 seconds
  - Core to peripheral temperature gap >3°C

Respiratory (one of the following)*

- $PaCO_2/FiO_2$ <300 in absence of cyanotic heart disease or pre-existing lung disease
- $PaCO_2$ >65 torr or 20 mmHg over baseline $PaCO_2$
- Proven need† or >50% inspired oxygen to maintain saturation >92%
- Need for nonelective invasive or noninvasive mechanical ventilation‡

Neurologic (either of the following)

- Glasgow Coma Scale score ≤11
- Acute change in mental status with a decrease in Glasgow score ≥3 points from abnormal baseline

Hematologic (one of the following)

- Platelet count <80,000/mm^3
- A decline of 50% in platelet count from highest value recorded over the past 3 days (for chronic hematology/oncology)
- International normalized ratio >2

Renal

- Serum creatinine ≥twofold upper limit of normal for age or twofold increase in baseline creatinine

Hepatic (either of the following)

- Total bilirubin ≥4 mg/dl (not applicable for newborn)
- ALT twofold upper limit of normal for age

From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child*, ed 3, St Louis, 2013, Mosby. Modified from Goldstein B et al: *Pediatr Crit Care Med* 6:2–8, 2005.

*Acute respiratory distress syndrome must include a Pao_2/FiO_2 ratio <200 mm Hg, bilateral infiltrates, acute onset, and no evidence of left heart failure. Acute lung injury is defined identically except the Pao_2/FiO_2 ratio must be <300 mmHg.

†Proven need assumes oxygen requirement was tested by decreasing flow with subsequent increase in flow if required.

‡In postoperative patients this requirement can be met if the patient has developed an acute inflammatory or infectious process in the lungs that prevents the patient from being extubated.

ALT, Alanine transaminase.

vasodilation, hypotension, and normal or high cardiac output, approximately half of children with septic shock present with severe peripheral vasoconstriction, high systemic vascular resistance, and low cardiac output.[25,34]

The child with septic shock has significant hypovolemia and maldistribution of blood flow that typically respond to aggressive fluid administration, antibiotics and titration of inotropes, vasopressors, and vasodilators. Therapeutic goals include restoring blood pressure, normalizing heart rate and capillary refill, and maintaining high cardiac index (3.3 to 6 L/min/m^2 body surface area [BSA]) and high oxygen delivery (more than 200 ml/min/m^2) BSA.[32-37] In fact, in a small but seminal report of outcomes of septic shock in children,[35] Carcillo, Davis, and Zaritsky showed that aggressive fluid resuscitation (more than 40 ml/kg administered within the first hour of therapy and more than 200 ml/kg administered during the first 8 hours of therapy) was associated with significantly higher survival than less aggressive fluid resuscitation. In the most recent consensus recommendations for hemodynamic support of children with septic shock,[32] the experts noted the reduction in mortality (from initial 35% to 40% mortality to about 2% to 8% mortality) associated with the implementation of their consensus therapy recommendations.[32,34] In fact, for every hour delay in the restoration of normal blood pressure for age and restoration of capillary refill less than 3 seconds, the child's mortality doubled.[25,32-34]

The ultimate goal of treatment of septic shock is to support adequate systemic oxygen delivery and organ perfusion and function. This requires careful titration of fluid administration, inotropic support, and vasoconstrictors or vasodilators to maximize systemic oxygen delivery and organ perfusion and function.

The terms *warm* and *cold septic shock* are imprecise terms and should be used only in conjunction with other descriptions of systemic perfusion and cardiovascular function. **Warm shock** is characterized by peripheral vasodilation, warm skin with flash capillary refill, bounding pulses, and wide pulse pressure. Warm shock was thought to be associated with hyperdynamic cardiovascular function and high cardiac output. These characteristics are most commonly seen in adults with septic shock.[25] **Cold shock** is characterized by peripheral vasoconstriction, cold skin with prolonged capillary refill, and decreased peripheral pulses. Cold shock is often associated with low cardiac output; these characteristics are present in almost half of children who present with septic shock.[25] However, cardiac output may be low, normal, or high regardless of skin temperature, perfusion, and pulses; these characteristics alone will not identify the cardiovascular support required. When inadequate systemic perfusion persists, the child likely needs more aggressive fluid administration and titration of vasoactive drug therapy.

Many adults and some children with sepsis generate a cardiac output that is higher than normal despite a fall in ventricular

ejection fraction. This high cardiac output may be associated with temporary adaptive ventricular dilation and an increase in ventricular end-diastolic volume, an increase in heart rate, and a fall in systemic vascular resistance. This low ejection fraction and ventricular dilation has not been documented in most children with septic shock. Most demonstrate severe hypovolemia, and cardiac function may be maintained or restored if fluid resuscitation is adequate.[25]

Kissoon, Orr, and Carcillo[34] describe the calculation of a *shock index* for children with septic shock. This shock index (heart rate ÷ systolic blood pressure) is high (2.4 or higher) with untreated or inadequately treated septic shock but falls with effective treatment of septic shock.

Obstructive Shock

Obstructive shock is inadequate cardiac output caused by an impediment to blood flow to or from the heart into the pulmonary or systemic circulation. Causes of obstructive shock in children include congenital heart defects (such as critical aortic stenosis and those with ductal-dependent pulmonary or systemic blood flow), tension pneumothorax, and pulmonary embolus. Obstruction to blood flow results in low cardiac output and circulatory collapse, typically with signs of peripheral vasoconstriction as adrenergic stimulation attempts to reduce blood flow to the skin, gut, and kidney and maintain adequate blood flow to the heart and brain. Signs of systemic or pulmonary venous obstruction are observed.

Additional clinical manifestations of obstructive shock are based on the cause of the obstruction. For example, the newborn with ductal-dependent pulmonary blood flow develops profound hypoxemia when the ductus arteriosus begins to constrict. If a newborn has ductal-dependent systemic blood flow, systemic pulses become faint or absent, extremities become cold and pale, and signs of pulmonary venous congestion develop when the ductus arteriosus begins to close. Tension pneumothorax produces signs of systemic venous obstruction and congestion, decreased breath sounds and chest expansion on the side of the pneumothorax, and shift of the mediastinum to the contralateral chest. Significant hypoxemia is present. When cardiac tamponade is the cause of the obstruction, signs of systemic or pulmonary edema, or both, develop with low cardiac output. When pulmonary embolus is the cause of the obstruction, hypoxemia, severe respiratory distress (or shortness of breath), and signs of right ventricular failure are observed.[3,16]

Treatment of obstructive shock focuses on restoration of systemic oxygenation and perfusion, and elimination of the obstruction to flow. To support systemic oxygenation and perfusion, providers must establish and maintain an adequate airway and support oxygenation and ventilation. Following establishment of vascular access, administration of a fluid bolus of 10 to 20 ml/kg of isotonic crystalloid may improve systemic perfusion; repeat if it is effective.[3,37] Diagnostic studies are limited to those essential to establishment of the diagnosis. Elimination of the cause of obstruction may require administration of prostaglandin E_1 (to reopen a constricted ductus arteriosus in newborns with ductal-dependent congenital heart disease), interventional cardiac catheterization for treatment of other defects causing obstruction, needle decompression of a tension pneumothorax or cardiac tamponade, and fibrinolytic therapy and anticoagulation (and possible embolectomy) for treatment of massive pulmonary embolus.[3,37]

Reperfusion and Inflammatory Injury

Reperfusion (reoxygenation) injury is cell damage caused by the restoration of blood flow and physiologic concentrations of oxygen to cells that have been exposed to injurious but nonlethal hypoxic conditions.[38] Ischemia causes changes in transmembrane permeability to sodium and calcium, and damage to intracellular organelles.[39] This damage triggers a proinflammatory and procoagulant response that can be very similar to that described for septic shock (described previously).

Restoration of oxygen delivery to extremely ischemic tissues produces highly reactive oxygen intermediates (e.g., free oxygen radicals and superoxide) that damage cell membranes, denature proteins, and disrupt chromosomes (see Chapter 2).[39] The amount of free oxygen radical produced is directly related to the severity and duration of the ischemic period. The reperfusion process is most likely to affect endothelial cells of the microvasculature, compromising organ perfusion after shock resuscitation.[38,39]

An ischemic insult activates white blood cells, priming monocytes and macrophages and contributing to the release of inflammatory mediators or cytokines, including TNF, IL-1, IL-6, IL-8, and platelet-activating factor. These cytokines in turn contribute to vasodilation, increased capillary permeability, and altered platelet function. The ultimate result is a maldistribution of blood flow and a compromise in organ perfusion.[38,39] The role of these mediators is summarized in Table 7-5. Chapter 48 includes a more comprehensive discussion of MODS.

Signs of organ dysfunction include but are not limited to lactic acidosis, oliguria, and an acute alteration in level of consciousness (e.g., decrease in Glasgow Coma Scale score of 1 point or more); hypoxemia, hypotension, poor capillary refill, or shock plus signs of coagulopathy, respiratory, renal, or hepatic dysfunction, or neurologic dysfunction. Gut injury and inflammation may enable translocation of gram-negative bacteria or endotoxin into the bloodstream, and may contribute to gastrointestinal bleeding.[5] Box 49-4 contains information on other potential signs of organ system failure in children.

Several scoring systems are available to characterize the severity of illness in critically ill children with organ dysfunction. These include the Pediatric Logistic Organ Dysfunction (PELOD) scoring system[40] and the Pediatric Multiple Organ Dysfunction Score (P-MODS).[40-42] These scoring systems may be useful as prognostic indicators when they are used for several days. Important differences exist between neonates and children in terms of mortality associated with specific organ failures and with specific PELOD scores.[41]

Evaluation and Treatment of Shock

The goals of treatment of shock are maximization of oxygen delivery and minimization of oxygen demand. The airway, oxygenation, ventilation, and perfusion must be supported. Reduction of oxygen demand requires treatment of fever and pain. In

BOX 49-5 MOST COMMON PEDIATRIC DYSRHYTHMIAS

addition, the child should be kept warm and shivering should be prevented. Blood components and, perhaps, intravenous fluids should be warmed before administration to young infants and children with hypothermia. Fear and pain increase oxygen consumption, so care must be taken to reassure the child and treat pain as indicated.

As noted, all children in shock require support of airway, oxygenation, and ventilation. Specific treatment of hypovolemic shock is volume resuscitation. Treatment targeting cardiogenic shock requires titration of fluid administration to optimize cardiac preload, but vasoactive drugs are needed to improve myocardial function and vasodilators or vasoconstrictors may be needed to support systemic perfusion. Specific management of septic shock includes administration of antimicrobial therapy, fluid resuscitation, and initiation of vasoactive support within the first hour of care following initial medical contact. Treatment specific to obstructive shock includes elimination of the cause of the obstruction to blood flow.

To evaluate and support airway patency and ventilation the child is positioned in a manner that supports maximal airway patency, and the provider then assesses airway and ventilation. Humidified supplementary oxygen is given as needed at up to 10 to 15 L/min by nonrebreathing mask or bag-mask ventilation. An advanced airway is placed in children *before* respiratory deterioration or arrest complicates shock management. Oxygenation is monitored continuously through pulse oximetry.

The child's heart rate must be adequate to support effective cardiac output and systemic perfusion. The most common pediatric dysrhythmias are listed in Box 49-5. Treat bradydysrhythmias and extreme tachydysrhythmias promptly. Pharmacologic therapy, pacing, or synchronized direct current (DC) cardioversion may be required.

The rhythms associated with loss of pulses ("arrest" rhythms) include asystole, electromechanical dissociation (EMD), pulseless ventricular tachycardia, and ventricular fibrillation. Regardless of electrocardiogram (ECG) findings, provide cardiopulmonary resuscitation—including cardiac compression—when pulses are lost or if, despite support of oxygenation and ventilation, the child demonstrates a heart rate less than 60/min with poor perfusion.

Adequate vascular access is needed to establish hemodynamic monitoring and to provide volume and inotropic support as needed. Once systemic perfusion is restored, transfer to a pediatric intensive care unit is advised.

Volume resuscitation is designed to restore intravascular volume relative to the vascular space and to optimize ventricular preload. The specific fluid selected and route of administration are determined by the child's clinical condition. In general, isotonic **crystalloids** (isotonic salt-containing solutions, such as normal saline or lactated Ringer's solution) or **colloids** (protein-containing fluids, such as albumin or blood) are administered in boluses of 20 ml/kg (or 10 ml/kg of packed red blood cells) given over 5 to 20 minutes for hypovolemic and septic shock. If cardiogenic shock (myocardial dysfunction) is present, smaller fluid boluses (5 to 10 ml/kg) are administered over about 10 to 20 minutes. Hypotonic fluids should not be administered.[3,37] After each bolus, reassess systemic perfusion and administer additional fluids if indicated.

Children in septic shock require a large volume of intravenous fluid to restore and maintain systemic perfusion. More than 40 ml/kg in fluid boluses will likely be required during the first hour of volume resuscitation, and a total of 200 ml/kg or more may be required during the first several hours of therapy.[3,32,34,35,37] In fact, rapid volume administration, particularly during the first hour of therapy, has been linked with improved survival in hypotensive children in septic shock.[33] An algorithm for the treatment of septic shock, based on the recommendations of the American College of Critical Care Medicine and the Pediatric Advanced Life Support course, is presented in Figure 49-2.

Unless shock is mild or responds immediately to volume therapy, insertion of a central venous (monitoring) catheter is advisable. Several multilumen catheters are available in pediatric sizes that enable simultaneous monitoring of central venous pressure and administration of fluids. Continuous or intermittent monitoring of the superior vena cava $S_{CV}O_2$ will enable evaluation of the balance between the child's oxygen delivery and oxygen consumption. If cardiac output is adequate, oxygen saturation in the SVC will be approximately 25% to 30% lower than the arterial oxygen saturation. A larger arterial venous oxygen saturation difference suggests inadequate oxygen delivery (caused by inadequate arterial oxygen content or inadequate cardiac output or both) or excessive oxygen demand.[3]

Monitoring of the volume of urine output and specific gravity is useful in determining the child's response to fluid therapy. A urinary catheter should be inserted if shock is present unless the child has sustained pelvic trauma or a urethral tear is suspected. All sources of fluid intake and output should be monitored and recorded hourly or more frequently if needed.

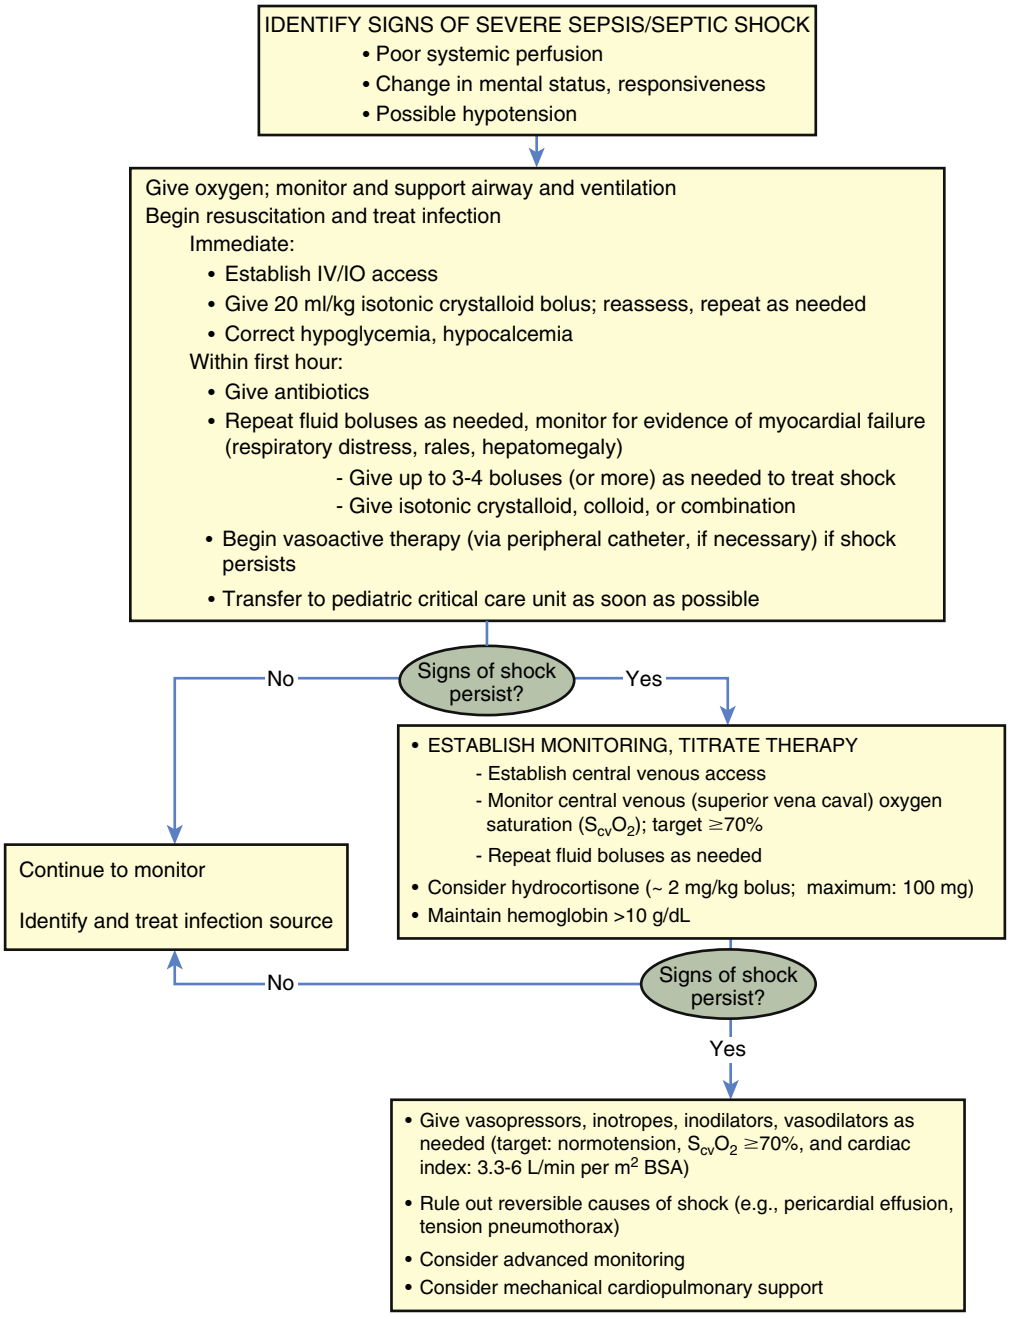

FIGURE 49-2 Hemodynamic Support in Pediatric Septic Shock. *BSA,* body surface area; *IO,* intake/output; *IV,* intravenous. (From Perkin RM et al: Shock, cardiac arrest and resuscitation. In Hazinski MF, editor: *Nursing care of the critically ill child,* ed 3, p 126, St Louis, 2013, Mosby; data from Brierley J et al: *Crit Care Med* 37:666–688, 2009.)

An intra-arterial line should be inserted if shock persists. This enables reliable, continuous evaluation of arterial pressure. Noninvasive oscillometric blood pressure–monitoring devices may not accurately measure low or rapidly falling blood pressures and may *overestimate* the blood pressure,[43] particularly in trauma patients.[44]

Insertion of a pulmonary artery catheter may be considered if the child demonstrates shock that is unresponsive to volume and vasoactive drug support. A pulmonary artery catheter with thermodilution cardiac output thermistor, a fiberoptic pulmonary artery catheter, or both can enable continuous monitoring of mixed venous oxygen saturation or continuous monitoring of cardiac output. Quantification of these variables can be particularly helpful if precise tracking of hemodynamic measurements is desired. This may be necessary in the care of the child with septic shock or MODS.

The optimal hemoglobin threshold for transfusion in critically ill children is unknown. In a multicenter trial of critically ill children, a hemoglobin red-cell transfusion threshold of 7 g/dl decreased transfusion requirements without increasing adverse outcomes.[45] However, that study excluded premature infants and children with severe hypoxemia, hemodynamic

instability, active blood loss, and cyanotic heart disease. A more recent publication from the same researchers[46] recommends higher transfusion thresholds (9 to 12 g/dl) for children with cardiac or respiratory disease, with the highest thresholds for children with cyanotic congenital heart disease and those with hemodynamic instability.

Administration of blood or blood component therapy is needed to treat hemorrhage or severe coagulopathies. A "normal" hematocrit does not rule out the possibility of hemorrhage; the hematocrit typically falls in a person who has sustained whole blood loss after the blood loss is replaced with crystalloids or colloids. In general, 10 ml/kg boluses of packed red blood cells are used for every second or third fluid bolus needed to treat significant blood loss.[14,15,37]

Transfusion for the child with chronic anemia and shock must be accomplished slowly to prevent hypervolemia and further deterioration in myocardial function. Administration of packed red blood cells at a rate averaging 3 to 5 ml/kg/hr over several hours may be well tolerated, particularly if it is preceded and followed by administration of diuretics.[47] If severe anemia is associated with severe hypervolemia and myocardial dysfunction, an exchange transfusion may be required. If a coagulopathy is present, administer specific blood component therapy necessary to prevent or treat hemorrhage.

Hypoxemia, metabolic acidosis, and electrolyte imbalances depress myocardial function and must be corrected when shock is present. Administer oxygen during resuscitation of the child in shock and be prepared to institute noninvasive pressure support ventilation or mechanical ventilation when needed.

The child's serum glucose concentration should be monitored using rapid bedside testing. Hypoglycemia requires glucose administration; continuous infusion is preferred to repeated intermittent bolus therapy. If severe hyperglycemia develops, insulin administration may be indicated to reduce the serum glucose concentration to less than 150 to 180 mg/dl. Although tight glycemic control has been linked with improved survival in critically ill children,[48] it also caused frequent episodes of hypoglycemia. The relative risks of severe hyperglycemia versus unintentional hypoglycemia have not been established.[49] In a recent survey, pediatric intensivists reported management of hyperglycemia with insulin therapy; the preferred blood glucose target range was 90 to 140 mg/dl.[50] A randomized clinical trial of pediatric glycemic control is needed.

During resuscitation, providers must avoid acute or severe alterations in the serum sodium concentration.[3,11,37] Acute changes in serum sodium alter the serum osmolality and result in fluid shifts into and out of the vascular spaces. Such fluid shifts can be associated with neurologic complications including seizures, cerebral edema, and intracranial hemorrhage.[11]

Alterations in serum potassium concentration may affect myocardial contractility and conduction. However, children are far less sensitive than adults to minor changes in serum potassium concentration. Hypokalemia may result from inadequate potassium administration during volume therapy or from excessive potassium losses caused by drug therapy (e.g., furosemide). The serum potassium concentration falls in the presence of alkalosis; this represents an intracellular shift of potassium and is corrected when the pH is normalized. Treat true hypokalemia with an infusion of potassium chloride at a dose equivalent to 0.5 to 1 mEq/kg administered over several hours.[11]

Hyperkalemia may result from excessive potassium administration, reduced potassium excretion (e.g., in renal failure), or massive cell lysis (e.g., tumor lysis syndrome). Serum potassium concentration also rises when acidosis develops; the rise in serum potassium is caused by a shift of potassium from the intracellular to the vascular space (i.e., exchanged for vascular H^+) and falls when the serum pH is corrected.[11]

Both ionized and total calcium concentration should be monitored, and documented hypocalcemia must be treated. Note that the ionized serum calcium falls with alkalosis and rises with acidosis. Serum ionized calcium concentration is often low (less than 4.5 mEq/L) in children with septic shock.[11]

Hypercalcemia may be observed in children with some malignancies, including acute lymphocytic leukemia, lymphomas, and soft tissue sarcomas. Malignant cells often secrete a parathormone-like substance that stimulates bone reabsorption, release of calcium, and rapid cell turnover. Although mild hypercalcemia is not life threatening, extreme hypercalcemia (total serum calcium approaching 19 to 20 mEq/L) may produce renal and cardiovascular complications.[47]

Table 49-7 summarizes drug therapy for children in shock. If oxygenation, ventilation, heart rate, and intravascular volume are appropriate and myocardial function and systemic perfusion remain poor, vasoactive drug therapy with inotropes is indicated.

Emerging Therapies for Shock and Sepsis

Prevention of shock is important. Prevention of trauma (injury prevention) and treatment of dehydration can eliminate the two leading causes of hypovolemic shock in children. *Haemophilus influenzae* sepsis and meningitis have been nearly eradicated in the United States since the introduction and widespread use of *H. influenzae* vaccine for infants, and immunization against *Neisseria meningitidis* (the causative microorganism of meningococcal sepsis and meningitis); pneumococcus vaccine may similarly reduce the incidence of pneumococcal infection and sepsis. The incidence of septic shock from hospital-acquired infections, such as ventilator-associated pneumonia or catheter-related bloodstream infections, is decreasing with the use of quality improvement approaches.[20]

Advances in shock therapy have been made in recent years, and several show promise for continued improvement in treatment. First, there is a better understanding of resuscitation goals with an appreciation of the need to target high, rather than normal, cardiac output and oxygen delivery during resuscitation.

Trauma resuscitation has become more targeted in adults and children. In the prehospital setting, prehospital fluid resuscitation is reserved for children with signs of shock. If penetrating trauma is associated with hypovolemic shock, the child requires urgent surgical intervention, so delays during transport are minimized.

Because massive transfusions can produce immunologic and coagulation complications, the surgical approach to trauma has changed to include staged surgical repair of significant

TABLE 49-7 PEDIATRIC VASOACTIVE DRUGS FOR THE TREATMENT OF SHOCK*

DOSE	EFFECTS	CAUTIONS
Sympathomimetics		
Dobutamine: 2-20 mcg/kg/min	Selective β-adrenergic effects, increases cardiac contractility and also increases heart rate (this latter effect is variable); β_2 effects produce peripheral vasodilation; no dopaminergic or α-adrenergic effects	Extreme tachyarrhythmias have been reported, particularly in infants; hypotension may develop; may produce pulmonary vasoconstriction
Dopamine: 1-5 mcg/kg/min	Dopaminergic effects predominate, including increase in glomerular filtration rate and urine volume	Can produce extreme tachyarrhythmias; can result in increase in pulmonary artery pressure; inhibits thyroid-stimulating hormone and aldosterone secretion
Dopamine: 2-10 mcg/kg/min	Dopaminergic effects persist and β_1 effects are seen, especially an increase in heart rate	As above
Dopamine: 8-20 mcg/kg/min	α-Adrenergic effects dominate	As above
Epinephrine: 0.05-0.15 mcg/kg/min	Endogenous catecholamine, which produces α, β_1, and β_2 adrenergic effects; at low doses, β_1 effects dominate	Will increase myocardial work and oxygen consumption at any dose; splanchnic constriction will occur at even low doses
Epinephrine: 0.2-0.3 mcg/kg/min	α-Adrenergic (vasoconstrictive) effects dominate	As above
Isoproterenol: 0.05-0.1 mcg/kg/min	β-Adrenergic effects; β_1 effects may result in rapid increase in heart rate; β_2 effects may produce peripheral vasodilation and also may effectively treat bronchoconstriction	Monitor for tachyarrhythmias, hypotension; will increase myocardial oxygen consumption
Norepinephrine: 0.05-1 mcg/kg/min	Endogenous catecholamine with α- and β-adrenergic effects; produces potent peripheral and renal vasoconstriction; can increase blood pressure	May cause tachyarrhythmias, increased myocardial work, and increased oxygen consumption; may result in hepatic and mesenteric ischemia
Vasopressin		
Vasopressin: 0.2 to 2 milliunits/kg/min (0.0002 to 0.002 unit/kg/min)	Antidiuretic hormone analog that acts on vasopressin receptors; produces peripheral and splanchnic vasoconstriction; also used to treat GI hemorrhage for this reason	May cause hypertension, bradycardia
Phosphodiesterase Inhibitors and Inodilators		
Inamrinone: Loading dose 0.075 to 0.1 mg/kg (75 to 100 mcg/kg) slowly Infusion: 5-10 mcg/kg/min	Nonadrenergic inotropic agent that produces phosphodiesterase inhibition and increase in intracellular cyclic adenosine monophosphate (cAMP); intracellular calcium uptake also is delayed; these effects result in improved cardiac contractility and vasodilation	Monitor for arrhythmias (especially accelerated junctional rhythm, junctional tachycardia, and ventricular ectopy); may produce hypotension (especially if patient is hypovolemic), liver and GI dysfunction, thrombocytopenia, and abdominal pain; experience in children is limited and recent
Milrinone: Loading dose: 0.05 mg/kg (50 mcg/kg) over 10-60 min Infusion: 0.25-0.75 mcg/kg/min	As above	Reduce dose when renal dysfunction present
Vasodilators		
Nitroglycerin: 0.25-0.5 mcg/kg/min; increase as tolerated to maximum 10 mcg/kg/min (adolescents, 5 mcg/min; *note* **not** per kg per min)	Arterial and venodilator	Is absorbed by polyvinyl chloride tubing; use special infusion set
Nitroprusside: 0.3-0.5 mcg/kg/min; titrate up to 8 mcg/kg/min (max. infusion dose: 8-10 mcg/kg/min)	Arterial and venodilator	Light sensitive; use special infusion set or cover tubing when infusion slow; may produce thiocyanate and cyanide toxicity, particularly for higher doses or prolonged infusion

*Infusion rate = ml/hr = Weight (kg) × Dose (mcg/kg per min) × 60 min/hr ÷ concentration (mcg/ml).

GI, Gastrointestinal.

injuries (e.g., liver and bowel injuries). The initial surgery is performed to stabilize the child, and, if needed, subsequent procedures repair the injury. This multistage approach, based on battlefield experiences, reduces the volume of blood products administered and has been linked with reduced morbidity and mortality.[15]

We now have a better understanding of the pathophysiology of septic shock in children,[32] appreciating the critical role that immediate antibiotics, early and aggressive fluid resuscitation, and vasoactive therapy play in the outcome of pediatric sepsis.[32-36] Such resuscitation should be provided during the first hour of therapy; every hour of delay has been reported to result in a 40% increase in mortality.[33]

Goals for management of pediatric septic shock are to restore the child's heart rate and blood pressure to normal for age, to achieve targeted perfusion pressure (mean arterial pressure – CVP) of about 55 to 65 mmHg, to reduce capillary refill to less than 2 seconds, and to support a cardiac index of 3.3 to 6 L/min/m^2 body surface area, and to maintain the SVC's $S_{CV}O_2$ at 70% or higher.[32,33-37] This goal-directed therapy, targeting an $S_{CV}O_2$ of 70% or higher in children, has been shown to substantially reduce mortality (by two thirds in one study) and organ failure.[36]

In an excellent and very concise summary of the management of the child in septic shock, Kissoon, Ort, and Carcillo suggest calculation of a *shock index,* dividing the child's heart rate by the child's systolic blood pressure (heart rate [HR] ÷ systolic BP). This shock index can serve as an indicator of left ventricular ejection, and should fall (e.g., from 2.25 to 1.75) in the first hour of effective management.[34]

Therapeutic hypothermia suppresses proinflammatory mediators and may enhance anti-inflammatory mediators.[51,52] Mild to moderate induced hypothermia (to 32° to 34° C [89.6° to 93.2° F]) has been shown to increase survival in neurologic outcome in neonates with hypoxic-ischemic encephalopathy[53] and in comatose, hemodynamically stable adults following resuscitation from cardiac arrest.[54] It is possible that such therapy may be helpful for victims of shock, particularly those with MODS. However, it is important to note that the control groups in these neonatal and adult hypothermia studies were all febrile. We know that fever develops following resuscitation from cardiac arrest and that fever is associated with unfavorable neurologic outcome.[55] While we await the results of multicentered clinical trials of therapeutic hypothermia in children, it is important to treat fever following resuscitation.

It soon may be possible to tailor sepsis and other critical therapies through the use of genetic profiling of the microorganism[23] and of the child.[22] Prospective identification of genetic markers for risk of sepsis and responsiveness to therapy may enable individual tailoring of surveillance and interventions to maximize survival and minimize risks from those therapies that are unlikely to be effective.

Finally, several devices are available that enable noninvasive or minimally invasive calculation of cardiac output and index, stroke volume, and circulating blood volume in children.[3] As providers gain experience with the use of such devices and more published data are available about their reliability, we will have more tools to confirm clinical assessment and monitor response to therapy.

BURNS

Management of pediatric burn injuries requires an understanding of the differences that exist in this population related to etiology of injury, growth and development, physiology, and clinical course. In 1988 the American Burn Association established criteria to guide transfer of a patient to a specialized burn center. These criteria remain a standard in burn care and are based on complex management issues related to treatment of acute burns and the long-term rehabilitation needs of children.[56]

Burn injuries in children often are preventable and often are the result of inadequate supervision, curiosity, inability to escape the burning agent, or intentional abuse. **Scald injuries** (i.e., hot water, grease, other) are most common among young children, whereas flame burns are more prevalent among older children.[57] A child exposed to hot tap water at 60° C (140° F) for 3 seconds will sustain a third-degree burn.[58]

A child's skin is thinner and thus more susceptible to injury than an adult's. The extent of injury is determined by the temperature of the burning agent and the duration of exposure. Because very young children may be unable to escape the heat source, the depth of the injury is likely to be greater. The kitchen also is a common site for burn injury and often involves pulling over dishes or appliances containing hot liquids. These are common burn injury sources for children 2 years of age and younger.

Although **child abuse** can occur at any age, young children are particularly vulnerable to serious injury. Approximately 10% of all forms of abuse cases in the United States are caused by burning.[59] Burns that may suggest physical maltreatment include: (1) patterned burns, (2) classic forced immersion burn pattern with sharp stocking or glove demarcation and sparing of flexed protected areas, (3) splash/spill burn patterns not consistent with history or developmental level, and (4) cigarette burns. Abuse is suggested with: (1) incompatible history and physical examination; (2) incompatible burn and developmental level; (3) bilateral or mirror image burns; (4) localized burns to genitals, buttocks, and perineum (especially at toilet-training stage); (5) evidence of excessive delay in seeking treatment; and (6) presence of other forms of injury.[60] Forced immersion in hot water typically presents with deep symmetric injuries lacking any evidence of splash wounds (Figure 49-3). By contrast, a pull-down splash burn usually has a triangular pattern with immediate skin contact reflected as the area of greatest burn injury. The burn injury then forms an arrow pointing downward. **Contact burns** also may be intentionally inflicted by contact with cigarettes or other hot objects such as curling irons. Young children may inadvertently grasp a hot object. However, the pattern of injury will be confined to the palm. Burns to the dorsum of the hand are viewed with suspicion.[59,60]

Children 3 to 8 years of age are most often injured by flame during fire play. Lighters and matches ignite clothing and cause house fires. Young children may run when clothing ignites and increase the severity of injury. Approximately 50% of all deaths

FIGURE 49-3 Burn Pattern Typically Seen After Forced Emersion in Hot Water.

FIGURE 49-4 Commissure Burn Resulting from Biting an Electrical Wire.

in burn children are caused by inhalation injury.[61] Escape from a burning residence or motor vehicle is often delayed because young children cannot cognitively comprehend the circumstances or physically remove themselves from the danger. **Flame burns** involving flammable liquids, especially gasoline, are more common in older children.

Although flame and scald burns account for the majority of thermal injuries in children, **electrical burns** result from direct contact with high- or low-voltage current. Most commonly these injuries occur as a result of risk-taking behavior on the part of young males. Trauma from contact with electrical energy results from the passage of current through vital organs, muscle compartments, and nerve or vascular pathways. Very young children are at risk for injury from chewing on electrical cords or inserting objects into electrical outlets (Figure 49-4). Lightning strikes also account for some electrical burns. **Chemical burns** occur most often in an industrial setting for the adult. At home, children may be burned by swallowing corrosive agents. The type of causative agent has important implications for the evaluation, treatment, and prognosis of the child.

Severity of Injury

The severity of burn injury is assessed based on the percentage of the total body surface area (TBSA) involved. Use of the standard

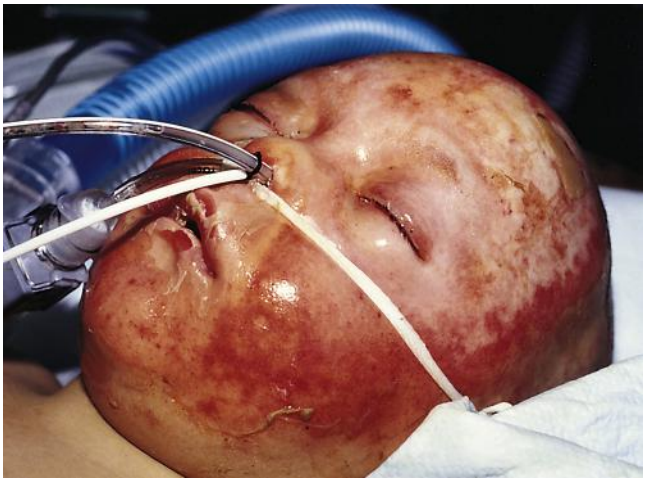

FIGURE 49-5 Areas of Indeterminate Depth of Injury in a Young Child.

Rule of Nines results in inaccurate calculation of the percentage of TBSA involved in children. Although the infant's trunk and arms are of roughly the same proportion as the adult's, the head and neck make up 18% of TBSA and each lower extremity is 14% of TBSA. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years.[58] Various charts are available that assign body proportions to children of different ages. These are generally used in pediatric burn facilities and do accurately compute the extent of burn injury.

Because burn trauma represents a three-dimensional wound, the severity of injury is assessed also in relation to the **depth of injury.** The etiology of the burn and the duration of contact with the burning agent are important considerations in determining the depth of injury. In general, the more intense the heat source and longer the contact, the deeper the resulting injury; however, infant skin is extremely fragile and more likely to sustain a deeper burn. This makes the estimation of the depth of burn difficult in very young children, especially following scald injuries (Figure 49-5). Intentionally inflicted burns tend to be more severe because contact with the burning agent is prolonged. Electrical injuries also may mask the extent of damage on initial assessment. Visible tissue damage may appear minimal despite severe injury to underlying structures.

Another important factor in assessing the severity of injury is the victim's age. Children younger than 2 years have a significantly higher risk for associated morbidity and mortality after sustaining a burn injury. They have not achieved maturity of the immune system and are at increased risk for infection and sepsis. In addition, very young children are intolerant of rapid fluid shifts and demonstrate immature renal function, which negatively affects their ability to retain sodium and water (see Shock).

The areas of the body injured are another consideration when assessing the severity of the burn. Burns of the hands, feet, and perineum and across joints carry the potential for scar formation and contracture that may interfere with function as well as growth and development. Specialized care is required to preserve maximal function. In addition, burns to the face and neck may result in airway compromise as well as deformity caused by damage to delicate cartilage of the nose and ears.

Concomitant injuries may be suggested by the circumstances of the burn and should always be investigated; for example, initially burns do not bleed. Bloody drainage suggests another source of trauma. Fractures may result from jumping from a window to escape a house fire. Electrical injuries and motor vehicle accidents often result in associated trauma. Any suspicion of intentionally inflicted burns should alert the burn team to assess for other injuries.

PATHOPHYSIOLOGY, CLINICAL MANIFESTATIONS, AND TREATMENT. Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities. Along with recognition of changes in the pathophysiology with a burn injury, clinical manifestations are apparent in all organ systems. Although the cutaneous trauma is the initiator of the chain of responses, it is important to consider all of the likely consequences of the injury. An awareness of the changing patterns of convalescence and the development of complications assists in the identification and early treatment of potential sequelae.

Integument

The local response manifested in the area of trauma includes cellular destruction and damage. Progressive injury caused by **dermal ischemia** may result from ineffective initial management, especially inadequate or delayed resuscitation. An increase in the permeability and hydrostatic pressure of the capillaries results in the loss of fluid, proteins, and electrolytes into the interstitial spaces. A diminishing intravascular oncotic pressure further enhances these losses and results in edema formation. Marked edema can result not only in the area of injury but also in unburned areas. Loss of substantial areas of skin has immediate and profound physiologic effects. Direct and evaporative fluid losses are seen immediately.[62] Although these losses are maximal in the immediate postburn period, they persist until wound closure.

Circulatory alterations also occur in the area of injury. Reduced blood flow and capillary stasis result from **hemoconcentration,** the release of thromboplastin and clot-activating factors from heat-damaged cells, reduced cardiac output, and edema formation. Circulation in the area of partial-thickness wounds ceases for 24 to 48 hours after injury, after which it is usually restored. Vascular supply in the area of full-thickness injuries is completely occluded and is not restored until granulation tissue forms or the wound is surgically repaired. The dry, leathery **eschar** provides an ideal environment for bacterial growth. Infection, trauma, or applying ice to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.

Vitamin D, an essential factor for proper formation of bone during growth and development, is an important nutrient in children to facilitate intestinal absorption of calcium. Vitamin D deficiency has been associated with adverse effects on the skeletal system, as well as the immune system. Vitamin D production may be compromised in burned children demonstrated by a high incidence of low-serum vitamin D levels. Burn wound scarring and lack of sunlight may limit cutaneous vitamin D biosynthesis.[63]

FIGURE 49-6 Escharotomy/Fasciotomy in a Severely Burned Arm.

Cardiovascular System

The marked reduction in cardiac output immediately following injury is accompanied by an initial increase in systemic vascular resistance. As fluid is lost into the interstitial spaces, a further reduction in cardiac output occurs, accompanied by vasodilation. Because the infant maintains cardiac output by increasing heart rate preferentially to stroke volume, extremely elevated heart rates result in a decreased filling time and a further reduction in cardiac output.[64] Adequate resuscitation returns cardiac output to normal levels in approximately 24 to 36 hours. Without fluid replacement, cardiac output continues to decrease and results in organ failure and death.

The inefficient and labile peripheral circulation of the infant further complicates management of the burn shock phase of treatment. The rapid fluid shift to the interstitial space and drying of the eschar results in compromised circulation and a resultant tourniquet effect in the extremities. Blood vessels and nerves become entrapped because the fascia cannot expand to accommodate the massive edema. Release of pressure is required to restore blood flow and preserve nerve function (Figure 49-6).

Constriction of the chest and impairment of respiratory excursion also may result, especially in the very young child, because of the increased pliability of the rib cage. Excessive fluid volume can contribute to a serious complication (increased intra-abdominal pressure) that may have an underestimated incidence in burned individuals. Although children with increased intra-abdominal pressure readings tended to be younger, larger TBSA injuries and full-thickness components were significantly associated with elevated pressures.[65] Increased **intra-abdominal pressure** has the potential to impair hemodynamics, renal function, hepatic malperfusion, and pulmonary dysfunction. Despite maintaining cardiac output with fluid replacement, renal function remains impaired in the presence of increased intra-abdominal pressure. Intra-abdominal pressure, as a stressor, can stimulate the neuroendrocrine system and elicit stress reactions directed at neutralizing the initial insult of the burn. Increases in the production and release of catecholamines, glucocorticoids, and beta-endorphins support the clinical finding of profoundly altered cardiovascular, pulmonary, and renal function.[66]

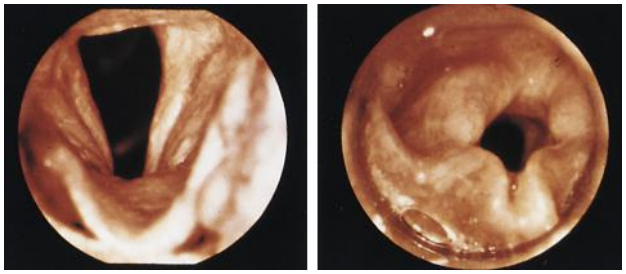

FIGURE 49-7 Airways. Adult airway *(left);* smaller pediatric airway *(right).*

Pulmonary System

The clinical manifestations of burn injury related to the pulmonary system include a variety of complications ranging from inhalation injury, pulmonary edema, and respiratory failure to aspiration of gastric contents and pneumonia. Inhalation injury has a negative, prolonged effect on pulmonary function that is associated with and remains a major determinant of increased morbidity and mortality.[67]

Anatomic differences in the pediatric airway affect the response to pulmonary complications, as well as therapeutic interventions. The infant airway is positioned anteriorly, making visualization of the cords more difficult. The difficult visualization is further compounded by the relatively large tongue and slanting vocal cords. A small degree of edema results in greatly increased work of breathing in the child (Figure 49-7). These considerations are particularly important during the resuscitation phase when progressive edema threatens to obstruct the airway. Significant edema results in impairment of respiratory function unless an artificial airway is inserted (Figure 49-8). Malposition of an endotracheal tube may result in inadvertent extubation, intubation of the bronchi, and atelectasis. Because of the relatively short length of the infant trachea, alterations of the position of the head and neck can affect tube position despite maintenance of the tube position at the teeth.[68-70]

Infants compensate for pulmonary compromise by increasing the respiratory rate. However, because the child possesses fewer type I muscle fibers, fatigue related to the increased work of breathing results in more rapid desaturation than in adults. The soft cartilage of the pediatric airway is prone to collapse in the presence of partial obstruction. Children with burns are at increased risk for these events because of underlying respiratory disease or injury.

Mechanical ventilation of severe inhalation injury is a dynamic and complex task.[71] Therapeutic interventions required for maintenance of pulmonary function have been implicated in postextubation stridor and barotrauma. Evidence suggests that barotrauma from mechanical ventilation may be minimized by protocols based on permissive hypercapnia. Moderate respiratory acidosis was well tolerated and ventilating pressures maintained below 40 cm.[72] The low incidence of mortality associated with this strategy suggests a reduction in ventilator-induced lung injury. In addition, high-frequency oscillatory ventilation (HFOV) in severe pediatric burn patients has significant, early, and sustained improvement in oxygenation. When HFOV is begun early in burn care, barotrauma is significantly reduced.[73]

FIGURE 49-8 Severe Facial Edema During Burn Shock.

The consequences of metabolic and physiologic changes occurring during the acute phase of injury remain apparent during convalescence. Severe burns result in a decrease in pulmonary function from restrictive and obstructive pulmonary disease evidenced by a reduction in pulmonary volumes and maximum voluntary ventilation lasting up to 8 years. At times, chest wall scarring in children caused by burns severely limits thoracic cage excursion.

Burn Shock

The pathophysiologic responses of burn injury result in **hypovolemia** and extracellular sodium depletion in the burn-injured individual. Manifestations for adults are discussed in Chapter 48. Hypotension is a late sign of shock in the child. A complete circulatory assessment, including heart rate and peripheral parameters, is a more reliable measure. Urine output is a reflection of end-organ perfusion and is therefore the most accurate monitor of the adequacy of fluid resuscitation. A urine output of 30 to 50 ml/hr in adults and 1 ml/kg/hr in children weighing less than 30 kg are the suggested endpoints associated with many resuscitation formulas. Fluid is titrated to maintain the output within the parameters.[58]

The fluid of choice for burn shock resuscitation should approximate the fluid lost from the circulating volume, for example, lactated Ringer's solution. Children require fluid resuscitation for smaller burns than do adults as a result of their limited physiologic reserves. The child's relatively greater ratio of body surface area to weight results in increased evaporative water losses and proportionately more fluid during resuscitation. Although **colloid replacement** during burn shock

resuscitation remains controversial, colloids may be required in the very young child who fails to respond to fluid replacement.[74] A component for **maintenance fluid** *must* be included in the calculation of fluid needs during resuscitation. Maintenance fluids represent the body requirements in the absence of burn injury.

Successful resuscitation depends on establishment of intravenous access. Although this is usually accomplished by peripheral or central venous cannulation, circulatory collapse may preclude timely administration of fluid replacement. Cannulation of veins in the pediatric population is further complicated by small vessels and increased subcutaneous fat. Children are good candidates for **intraosseous cannulation** when traditional venous access techniques fail. Blood, drugs, and fluid are readily absorbed by red marrow that drains into medullary venous channels and thus to the systemic circulation. This technique is most effective in children younger than 5 years, because red marrow is steadily replaced by yellow marrow in the limbs, making infusion more difficult, hence decreasing the infusion rate.[75] With proper care and removal as soon as other access is available, complications are minimal.

Fluid Resuscitation

Fluid resuscitation is generally required for children after thermal injuries in excess of 10% to 15% of the TBSA. Fluid is administered to compensate for fluid and electrolytes extravasating into the interstitial spaces. This replacement restores circulating volume, improves perfusion, and alleviates organ dysfunction associated with impaired circulation.

Various protocols have been proposed as guidelines for fluid administration. It is important to remember that any regimen serves merely as a guideline and will require adjustment based on the individual response of each child. Because the linear relationship between weight and surface area does not exist in children (surface area varies to weight as a two-thirds function), use of adult formulas result in under- or over-resuscitation.[76] A commonly used protocol is a modification of the Parkland formula. Children also tend to require relatively more fluids than adults because they have higher evaporative losses because of their body surface area-to-weight ratio. **Evaporative fluid loss** can be a significant contributor to hypovolemia in the burned child. This evaporative fluid loss continues until the burn wounds are closed. As in adults, inhalation injury also continues until burn wounds are closed. And as in adults, inhalation injury increases the magnitude of total body surface area injury; therefore, children with burn injuries require more fluids.[74]

Research suggests that in the acute phase of the burn injury children receive far more fluid resuscitation than calculated by the modified Parkland (Baxter) formula guidelines. This syndrome has been termed "fluid creep."[77] Onset maybe caused by higher fluid limits and increased use of opiates resulting in an increased abdominal pressure. The method to control fluid creep includes strict adherence to the modified Parkland formula. In children who have developed increased abdominal pressure, decompressive laparotomy may resolve the increased intra-abdominal pressure.[74]

Renal System

Loss of circulating volume into the interstitial spaces results in reduced renal blood flow and decreased glomerular filtration. An important measure of the adequacy of volume replacement is urine excretion. Sufficient volume replacement maintains urine output during resuscitation. Approximately 36 hours after injury, edema fluid begins to mobilize and output increases.

Children younger than 2 years of age lack the ability to concentrate urine because of the immaturity of the renal system and are, therefore, at increased risk for dehydration. In addition, the child has a relatively larger TBSA in relation to weight than the adult. Combined with limited physiologic reserves, increased fluid requirements are necessary for children during burn shock resuscitation and to compensate for evaporative water losses.[76]

Evidence of pigment in the urine results from the hemolysis of red blood cells. This is especially common after extensive electrical injuries and destroyed muscle from deep thermal injury. The release of **myoglobin** may occlude the kidney tubules and result in renal failure.

Gastrointestinal System

The gastrointestinal (GI) system plays an important role in the pathophysiology of burns. Alterations in blood flow result in decreased perfusion to the GI tract. Ischemia may cause erosion and necrosis of GI tissue. The GI response to a burn injury often includes mucosal atrophy, changes in digestive absorption, and increased intestinal permeability. Depending on the proportion of burn size, atrophy of the GI tract mucosa can occur immediately after injury. The atrophy results in gut barrier dysfunction leading to increased bacterial translocation and ultimately sepsis.[78]

Paralytic ileus occurs often after major burn injuries. Although digestion ceases in the stomach and the large bowel, the small intestine maintains motility and absorptive capacity. Intestinal motility returns as fluid losses are replaced unless irreversible necrosis of the bowel has occurred as a result of insufficient perfusion.

Immune Function

Burn trauma–induced immunosuppression results in increased susceptibility to infection and sepsis. Although the exact mechanisms responsible for this immunosuppression remain obscure, it is clear that complex interactions of the hypermetabolic response, nutritional support, bacterial translocation, and defects in both innate and acquired immune function are involved (Figure 49-9). In addition, young children are at increased risk for microbial invasion caused by an immature immune system and limited antibody production.

Deitch reported that wound- or gut-derived endotoxemia may be one of the mediators of the hypermetabolic response observed after thermal injury, and this finding remains undisputed.[79] When bacteria translocate from the gut or from the burn wound, endotoxin may affect immunologic response as inflammatory mediators are released. A further complication in the activation of inflammatory mediators is the release of toxic metabolites, such as oxygen free radicals.[80]

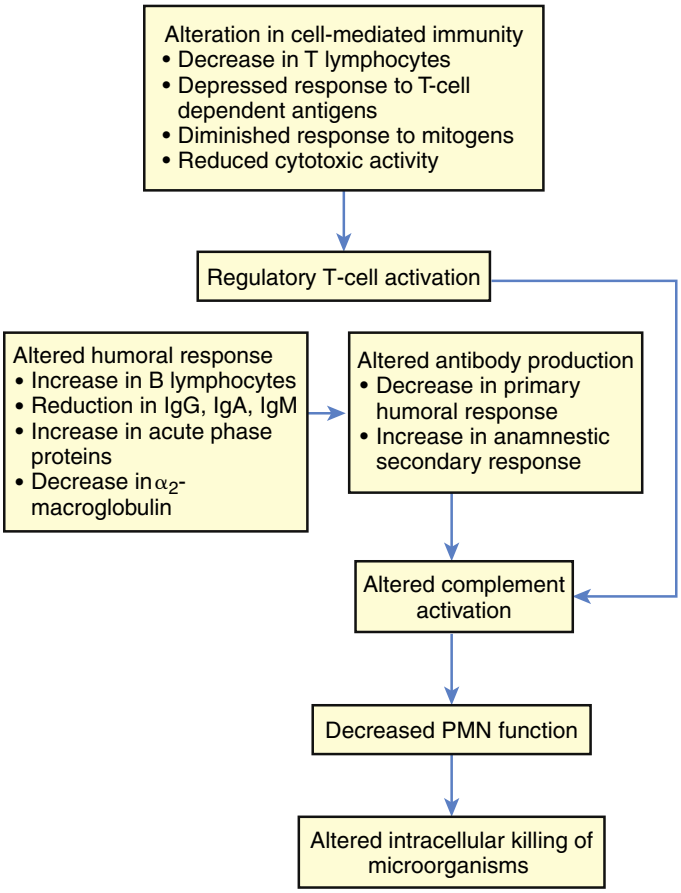

FIGURE 49-9 Altered Immune Function After Thermal Injury. Cell-mediated immunity, antibody production, humoral response. *PMN,* Polymorphonuclear leukocyte.

Circulating immunoglobulins may be affected by several factors, including age and the severity of injury.[81] Therapeutic interventions such as multiple transfusions, surgical procedures, and antibiotic and anesthetic administration also introduce elements that confound the evaluation of immunosuppressive effects. The immune system is activated systemically after a large burn injury with extensive tissue necrosis and may become ineffective or even self-destructive. Infections in burns may result in the loss of some components of innate immune function.[82]

An additional aspect of the immunopathologic consequence of a burn is the role of immunomodulatory cytokines that are suggested to regulate innate regulatory lymphocytes. Research regarding four cell types—NK (natural killer), natural killer T (NKT), gamma-delta T (γδ), and regulatory T (Treg)—indicates their central role in protective immunity.[83] In children with moderate to severe burn injury, cytokines have been found to increase inflammation by enhancing catabolism and hypermetabolism. In this immunomodulatory process the proinflammatory function of cytokines enhances protection from sepsis, and the anti-inflammatory function supports anabolism (i.e., tissue repair).[84]

Infection

Whereas shock and pulmonary compromise present the most immediate threat after burn trauma, local and systemic infections become the primary complication during healing. The burn wound initially is relatively free of pathogens; however, dead, avascular tissue and wound exudate provide a fertile environment for bacterial growth. Colonization of the wound is apparent by the fifth postburn day. Gram-positive microorganisms are usually recovered from cultures first, followed by opportunistic gram-negative bacteria. The impaired vascular supply to burned tissue enhances the proliferation of pathogenic microorganisms. Bacterial invasion results in thrombosis and a further impairment of circulation sufficient to convert a partial-thickness injury to a full-thickness wound.

Improvements in treatment have resulted in a reduction in wound infection. Aggressive excision and grafting of the wounds, improved nutritional support, and the development of microorganism-specific topical antimicrobials have contributed to this trend. However, the incidence of septicemia remains relatively constant. This is perhaps explained by the survival of children with burns of increasingly large body surface area. The burn wound serves as the site of primary invasion for the majority of instances of local or generalized infection. Because the burned child is immunosuppressed for many weeks after injury, maintaining wounds at low contamination levels by meticulous wound care decreases the frequency and duration of septic episodes caused by wound flora.[85]

Metabolism

Complex metabolic alterations are observed after burn injury. The extent of metabolic derangement is proportional to the magnitude of TBSA burn sustained. Wilmore demonstrated the linear increase in metabolic rate up to 2½ times normal resting energy expenditure.[86] As burn injury approaches 50% of TBSA, a plateau is reached, limiting further physiologic response to the trauma or other challenges such as infection.

A biphasic pattern of physiologic response is evident in thermally injured children. The initial **ebb phase** occurs during the immediate postburn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After the resolution of the shock and the restoration of circulating volume, the metabolic response shifts to a **catabolic (flow) phase** (Table 49-8). A state of **hypermetabolism** ensues, characterized by increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.

Increased blood flow to the wound supplies additional glucose necessary for tissue repair. Insulin levels are usually normal or even elevated but are inappropriately low in relation to glucagon. Catecholamines and glucocorticoids act as antagonists to insulin. This effect combined with a tissue resistance to insulin stimulates glycogenolysis and gluconeogenesis, thus increasing glucose flow from the liver.[65] In the child, glycogen stores for meeting the increased energy demands of the burn are limited. The initiation of protein and lipid catabolism for glycogenesis is accelerated. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.[87]

Metabolic rates slowly return to normal with wound closure. However, a reactivation of the hypermetabolic response may occur with sepsis or organ failure.

TABLE 49-8 METABOLIC ALTERATIONS FOLLOWING INJURY

RESPONSE	DOMINANT FACTORS	CLINICAL FINDINGS
Ebb response	Loss of plasma volume	Hyperglycemia
	Shock	Decreased oxygen consumption
	Low plasma insulin levels	Depressed resting energy expenditure
		Decreased blood pressure
		Cardiac output below normal
		Decreased body temperature
Flow response		
Acute phase	Elevated catecholamines	Catabolic
	Elevated glucagons	Hyperglycemia
	Elevated glucocorticoids	Increased respiratory rate
	Normal or elevated insulin levels	Increased oxygen consumption
	High glucagon/insulin ratio	Increased body temperature
		Redistribution of polyvalent cations such as zinc and iron
		Mobilization of metabolic reserves
		Increased urinary excretion of nitrogen, sulfur, magnesium, phosphorus, potassium
		Accelerated gluconeogenesis
Adaptive phase	Stress hormone response subsiding	Anabolic
		Normoglycemia
		Energy turnover diminished
		Convalescence

Hypermetabolism

The hypermetabolic response after burn injury profoundly alters the production and use of nutrients. As a consequence of these phenomena, caloric requirements increase dramatically. Advances in burn care have allowed the performance of indirect calorimetry and assessment of metabolic rate at the bedside. Nutritional support must have an increased metabolic rate factored in (increased by 10% to 20%) because of fluctuations in energy use associated with activity. Current recommendations suggest 1.5 to 2 g protein/kg/day for adults and up to 2.5 to 4 g protein/kg/day for children.[87]

In addition to age, body composition has been found to significantly affect the postburn course. Preexisting obesity in burn children has been associated with longer hospital stay and associated morbidity.[88] However, the heightened nutrient requirements of the burned child preclude a reduction in nutritional support during the acute phase of recovery. Aggressive nutritional therapy is critical to the recovery of these children, and programs designed to achieve ideal body weight should not be instituted until wound healing is achieved.

Metabolism of many micronutrients is greatly affected by burn injury. Micronutrient supplementation is necessary because vitamin and mineral requirements increase with the severity of the burn related to heightened protein synthesis, enhanced caloric expenditure, and increased micronutrient losses. Pre-burn status also indicates individual vitamin and mineral needs.[63] Hypermetabolism results in a rapid turnover in vitamins and trace minerals important in the wound healing and immune response. A deficiency of specific nutrients interferes with carbohydrate and nucleic acid metabolism, collagen formation, and immune function.

The **thermoregulatory response** after burn injury results in an elevation in core body temperature. Burned individuals strive for temperatures of about 38° C (100.4° F). Depressed or "normal" temperature may be indicative of overwhelming sepsis, or an exhausted physiologic capability to maintain temperature, and should be viewed as an ominous sign. Routine methods of heat conservation after a major burn injury are inadequate because of excessive heat loss through convection and evaporation.[88] Therapeutic intervention, such as operative procedures and dressing changes, and transport present situations requiring increased diligence to prevent inadvertent cooling. Infants are at increased risk for a precipitous drop in core body temperature caused by an inability to regulate heat loss by shivering. Heat is also lost because of evaporation of water from damaged skin surfaces. Infants and children are especially vulnerable because of the large surface area relative to metabolically active tissue.[77]

Nutritional Support

The heightened metabolic demands after burn injury combined with a poor appetite often necessitate supplementation of oral intake. Children with burns in excess of 20% of TBSA often require supplementation with tube feeding. Feeding does not need to be delayed pending resolution of paralytic ileus and the resumption of bowel sounds because the small bowel maintains motility and absorptive capability. A small-bore feeding tube placed in the duodenum provides a safe route for the delivery of essential nutrients. Parenteral hyperalimentation is reserved for those children who are unable to tolerate enteral support because of attendant risks of catheter sepsis and loss of intestinal integrity. Early enteral supplementation preserves gut

WHAT'S NEW?

Advances in Burn Wound Care

Ongoing research and development continues to focus on the burn wound dressing, providing more therapeutic options with major wounds. Impregnated silver dressings kill bacteria but because most are processed with a special layer, they are less painful to remove. Some of these products can be left on the wound for up to 2 weeks allowing less frequent dressing changes and more comfort for the individual. A new extracellular matrix (ECM) product is being researched for repair and remodeling of damaged tissues in a burn injury and other therapeutic wound care situations. Derived from porcine urinary bladder, this ECM technology contains a bimodal surface technology with naturally occurring collagens and proteins and maintains an epithelial basement membrane surface. An in vitro study demonstrated that urinary bladder ECM is the best basement membrane as compared to small intestine or liver ECM. Another study suggested that antibacterial activity exists within ECM and these low-molecular-weight peptides may help explain resistance to bacterial infection.

Data from Brennan A et al: *Tissue Eng* 12(10):2949–2955, 2006; Brown B et al: *Tissue Eng* 12(3):519–526, 2006.

mucosal integrity and improves intestinal blood flow, as well as motility.[63] Early initiation of enteral supplementation along with aggressive management of complications permits successful enteral alimentation in most burned children.

Severe burn injury causes exaggerated muscle protein catabolism, contributing to weakness and delayed healing. Many therapeutic strategies have been used to avert the hypermetabolic response and improve clinical outcomes. Pharmacologic agents, such as recombinant growth hormone, low-dose insulin, and testosterone, have been shown to improve muscle kinetics and wound healing. However, these can cause serious side effects. Investigators have found that anabolic steroid agents, along with nutritional support, improve muscle protein metabolism through enhanced protein synthesis efficiency in children and adults.[89] Outpatient follow-up should include regular weighing of the child and nutritional assessment to identify children at risk for further weight loss.

Wound Management

The goals of wound management include prevention of infection, removal of devitalized tissue, and closure of the wound (see What's New? Advances in Burn Wound Care). Burns that are clearly deep dermal or full-thickness injuries are surgically excised as soon as the child is hemodynamically stable after resuscitation. Early excision reduces the incidence of wound infection and systemic sepsis.[90-92] Coverage of the excised wound is necessary to achieve wound closure. The choice of a coverage technique depends on the availability of donor skin.

Split-thickness sheet grafts are selected for areas of maximal functional and cosmetic results (Figure 49-10). Children with very large burn injuries often do not have sufficient unburned skin available to facilitate use of the sheet graft. In these cases the surgeon uses a meshing technique to expand the available skin and increase the size of the graft. The pattern created heals by migration of epithelium from the meshed edges. Scar formation is increased, and the mesh pattern remains clearly visible (Figure 49-11). The color, texture, vascularity, thickness, and hair-bearing nature of the skin vary from one area to another. Site selection and depth of donor sites require careful consideration. Skin grafts for the face should be taken, if possible, from above the nipple line for best color match and "blush" ability.[91]

FIGURE 49-10 Split-Thickness Sheet Graft.

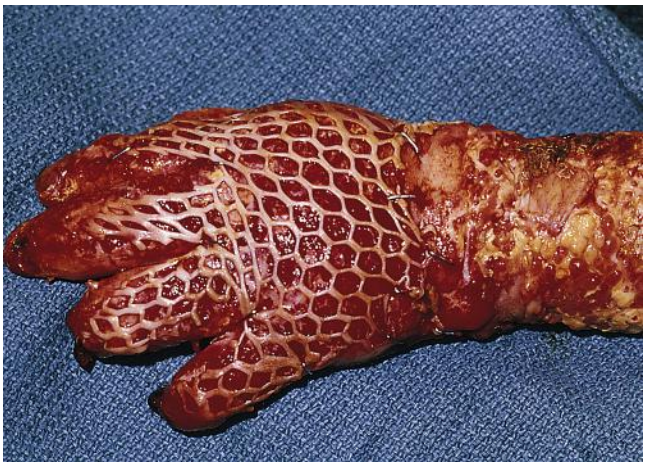

FIGURE 49-11 Meshed Autograft.

Scar Maturation

In normal epidermal healing, minimal disruption in skin color, texture, and thickness occurs. However, burn wounds that extend into the dermis are repaired through **scar formation** and may result in an overgrowth of dermal constituents (Figure 49-12, *A*). Accelerated collagen synthesis most likely begins with high levels of activity in granulation tissue. The **hypertrophic scar** consists of hypercellular and disorganized connective tissue that is erythematous, raised, and pruritic. Normal dermis contains thick fibers and fiber bundles running parallel to the surface. In the hypertrophic scar, the collagen is arranged in whorls and nodules that account for its inelasticity and increased turgor.[92] As the hypertrophic scar matures, collagen begins to orient in a more parallel fashion, and vascularity decreases (see Figure 49-12, *B*). Collagen synthesis is very active soon after wound closure, and alteration of the scar can be accomplished before strong cross-linking of the collagen is established.

FIGURE 49-12 Scar Maturation. **A,** Immature hypertrophic scar. **B,** Flat, mature scar after pressure therapy.

Although duration of wound healing varies among individuals, the length of time required to achieve wound closure is the most reliable predictor of hypertrophic scarring. Deeper burns demonstrate increased scarring caused by the formation of granulation tissue and prolonged healing time. Generally, darker-pigmented races are more susceptible to hypertrophic scarring.[92,93] Although age has not been found to be a predictor of hypertrophic scar formation, younger individuals are more susceptible to trauma and have greater skin tension and an accelerated rate of collagen synthesis. Increased tension with resultant trauma stimulates inflammation, which in turn results in the formation of additional collagen.

Scar tissue is metabolically active and highly vascular. Collagen is deposited in random patterns, and contraction of the scar can result in disabling deformities. The scar is active as long as it is raised, red, and firm. **Scar maturation** requires 1 to 2 years and depends on individual differences and compliance with the rehabilitation program. The mature scar is characterized by increased suppleness, flattening, and pigmented color.

Scar tissue does not grow and expand like normal tissue. Although massage therapy offers some benefit in stretching, functional limitation may develop as the child grows. This is particularly evident over joints. Reconstructive surgery is often necessary to restore anatomic integrity and to promote independent function.

Itching may occur at any time during burn wound healing. As a complication, healed skin may be scratched away in an effort to obtain relief. The combination of H_1 and H_2 antagonists may be used to control itching.[94]

Comfort Management

Pain management presents a significant challenge in the pediatric population. In addition to procedural pain, there is a component of background pain that is present without activity. Pain perception is also affected by the degree of emotional overlay or affective experience.[95] The measurement of pain is particularly challenging in young infants, who lack the language skills to express pain. A variety of tools, from physiologic monitors to behavioral analyses and analog scales, have been developed to measure pediatric pain. The quality of pain control in burn centers has improved along with the ability to assess pain in the pediatric population. Studies have documented pharmacologic as well as nonpharmacologic interventions that have improved the quality of pain control.[95]

Recovery from Burn Injury

Rehabilitation becomes the major focus of care once wound coverage has been achieved and continues until all reconstructive procedures have been completed. This phase may extend over many years in the pediatric population. Children require specialized management to ensure optimal functional and cosmetic results. Scar and contracture management is necessary for prolonged periods because of changes in body composition as the child grows and matures. Very young children present unique challenges because the small body size can be difficult to fit with pressure garments and splints, growth is rapid, and cooperation with the rehabilitation program is limited.

Infant skin is thinner, and the epidermis is more loosely connected to the dermis. This increases the risk of blistering, chafing, and rash formation. The infant also produces less sebum and sweat, which further exacerbates the propensity to skin irritation. Because scar tissue contains no sweat glands, these characteristics of the skin in growing children compound the difficulty in maintaining pressure on maturing scars while cooling the body.

Positioning and splinting to prevent contracture formation, as well as rehabilitative aspects of therapy, are instituted on admission and continue throughout the hospitalization. Physical therapy and occupational therapy provide exercise to maintain range of motion and function. Psychosocial support is very important for the child and the family. The information provided should be consistent and honest to allow clarification of concerns. In addition to the functional aspects of rehabilitation, attention must be directed to psychosocial needs and community reintegration.

A method to facilitate the transition from the hospital to the community is the school reentry program offered by many burn centers. These programs provide education for teachers and peers about the injury, appearance, and abilities of the returning child.

SUMMARY REVIEW

Shock and Multiple Organ Dysfunction Syndrome

1. Shock in children is present when there are signs of poor systemic perfusion, regardless of blood pressure.
2. Hypovolemic shock is the most common type of shock in children and it most frequently results from dehydration and trauma. Hypovolemic shock also may result from expansion of the vascular space, producing inadequate intravascular volume relative to the vascular space.
3. Hypotension is a sign of severe (preterminal), decompensated shock, referred to as "hypotensive shock."
4. Clinical manifestations of hypovolemic shock include inadequate systemic perfusion associated with intravascular fluid loss. Adrenergic compensatory mechanisms can produce tachycardia, redistribution of blood flow, peripheral vasoconstriction, cool extremities, delayed capillary refill, and oliguria.
5. Neurogenic shock is caused by a loss of vasomotor tone after severe injury to the spinal cord.
6. Clinical manifestations of neurogenic shock include warm skin, hypotension with a low diastolic blood pressure, and poor systemic perfusion. Tachycardia is not present.
7. Cardiogenic shock, with decreased cardiac output, is observed most commonly after cardiovascular surgery or with inflammatory diseases of the heart, such as cardiomyopathy and myocarditis. It is also found in children with obstructive congenital heart disease and those with drug toxicity or severe electrolyte or acid-base imbalances.
8. Clinical manifestations of cardiogenic shock include inadequate systemic perfusion despite adequate intravascular volume. Cardiac output is typically low. Adrenergic compensatory mechanisms, including peripheral vasoconstriction and decreased urine volume, are similar to those found in hypovolemic shock.
9. Once septic shock is present, immediate treatment is urgently needed. Therapy in the first hour includes aggressive fluid resuscitation (typically 60 to 80 ml/kg administered in first hour of therapy, and approximately 200 to 240 ml/kg in the first 8 hours of therapy). If the child does not respond to volume administration alone, vasoactive support must be initiated within the first hour of treatment. Antibiotics also must be administered within the first hour. Goals of therapy are to rapidly normalize the heart rate and blood pressure for age and to normalize capillary refill to less than 2 seconds. The child's shock index (heart rate/systolic blood pressure) should fall during the first hour of management if therapy is effective. Fluid and vasoactive therapy should support high cardiac output and oxygen delivery, maintaining the $S\bar{v}o_2$ at approximately 70%.
10. Sepsis is a systemic response to infection. It is present when manifestations of SIRS are observed. SIRS is present when the child demonstrates two or more of the following as an acute change from baseline values: altered temperature, altered heart rate, altered respiratory rate, and alteration in the WBC count. The newborn often develops hypothermia rather than fever as a sign of infection and may develop bradycardia instead of tachycardia.
11. Severe sepsis is present when there is evidence of SIRS and signs of organ dysfunction, hypoperfusion, or hypotension.
12. The development of septic shock is heralded when the child with severe sepsis develops signs of cardiovascular dysfunction. The child may become hypotensive despite adequate fluid resuscitation or require vasopressors to maintain blood pressure.
13. Reperfusion and inflammatory injury stimulate free oxygen radicals that can damage cell membranes, denature proteins, and disrupt chromosomes. This process likely affects endothelial cells and the microvasculature, causing MODS.
14. Lactic acidosis (i.e., rise in serum lactate) may be the most sensitive indicator of inadequate systemic perfusion in children; effective shock therapy should eliminate lactic acidosis.
15. The general goals of treatment for shock are maximization of oxygen delivery and minimization of oxygen demand. This requires support of airway, oxygenation, and ventilation. Support of cardiovascular function requires support of appropriate heart rate and rhythm, adequate intravascular volume, good myocardial function, and appropriate vascular resistance and distribution of blood flow. The child should be kept warm but fever must be treated promptly.
16. The signs of shock should lessen or disappear if management of shock is effective. The warmth of the child's extremities, briskness of capillary refill, quality of peripheral pulses, level of consciousness and responsiveness, urine volume, oxygenation, ventilation, and acid-base status should improve throughout shock therapy.

Burns

1. Burns in children are often the result of inadequate supervision, curiosity, inability to escape the burning agent, or intentional abuse.
2. Scald injuries are commonly seen in young children and result from exposure to hot water, grease, or other hot liquids, whereas flame burns are more prevalent among older children.
3. A child's skin is thinner and thus more susceptible to injury than adult skin. The kitchen and bathroom are common sites of burn injury.
4. Approximately 10% of all forms of child abuse cases in the United States result from burn injury.
5. Flame burns involving flammable liquids, most notably gasoline, are more common in older children. Risk-taking behaviors in young males can lead to electrical burns. Children may be exposed to chemical injury by swallowing caustic agents at home.
6. Use of the standard Rule of Nines results in inaccurate calculation of the percentage of TBSA in children. A modified Rule of Nines deducts 1% from the head and adds 0.5% to each leg for each year of life after 2 years of age.

SUMMARY REVIEW—cont'd

7. Major burn trauma involves all body systems, and the consequences of injury include shock, infection, hypermetabolism, organ failure, and functional limitations. These effects can be magnified in the pediatric population as a result of physiologic immaturity and age-related variation in treatment modalities.
8. Infection, trauma, or applying ice to the burn area may convert a partial-thickness injury to a full-thickness one, especially in young children, who have thinner, more delicate skin.
9. Marked reduction in cardiac output occurs immediately after injury and is accompanied by an initial increase in systemic vascular resistance. The inefficient and labile peripheral circulation of the infant complicates management of the burn shock phase of treatment. Constriction of the chest and impairment of respiratory excursion may occur in the very young child because of the increased pliability of the rib cage. Younger children are also more susceptible to increased intra-abdominal pressure.
10. The leading cause of death in children after burn injury, as in adults, is inhalation injury.
11. Children require fluid resuscitation for smaller burns than does the adult population as a result of limited physiologic reserves. Colloid replacement may be required in the very young child who fails to respond to fluid replacement.
12. Children younger than 2 years lack the ability to concentrate urine because of the immaturity of the renal system and are therefore at increased risk for dehydration. Because children have a relatively larger body surface area in relation to weight than adults, they require proportionately increased fluid during burn shock resuscitation to compensate for evaporative water losses.
13. Some children exhibit immunosuppression for a prolonged period after wound closure.
14. A biphasic pattern of physiologic responses is evident in the burn-injured child. The initial ebb phase occurs during the immediate postburn period and continues for 3 to 5 days. This phase is characterized by reduced oxygen consumption, impaired circulation, and cellular shock. After this phase and the restoration of volume, the metabolic response shifts to a catabolic, or flow, phase. This phase is characterized by hypermetabolism with an increased oxygen consumption and elevation of catecholamines, glucocorticoids, and glucagon.
15. Glycogen stores are limited in children, making it hard for them to meet the increased energy demands of the burn. This prolonged metabolic dysfunction may lead to loss of lean body mass and increased morbidity.
16. Although age was not found to be a predictor of hypertrophic scarring, children have greater skin tension and an accelerated rate of collagen synthesis.
17. Children require specialized management to ensure optimal functional and cosmetic results. Long-term scar and contracture management is necessary because of changes in body composition as the child grows and matures.

Pageburst Integrated Resources

As part of your Pageburst Digital Book, you can access the following Integrated Resources:

Chapter Summary Review

interactive review

Absolute polycythemia excessive red blood cell production; a physiologic response resulting from increased erythropoietin secretion in response to chronic hypoxia or as a symptom of polycythemia vera.

Absorption atelectasis see Atelectasis.

Acid maltase deficiency (glycogen storage disease type II or Pompe disease) an autosomal recessive metabolic disorder that damages muscle and nerve cells throughout the body by an accumulation of glycogen in the lysosome attributable to deficiency of the lysosomal acid α-glucosidase enzyme. The buildup of glycogen causes progressive muscle weakness (myopathy) throughout the body and affects various body tissues, particularly in the heart, skeletal muscles, liver, and nervous system.

Acne a common skin disease characterized by pimples on the face, chest, and back. It occurs when the pores of the skin become clogged with oil, dead skin cells, and bacteria.

- **Acne conglobata** severe cystic acne characterized by cystic lesions, abscesses, communicating sinuses, and thickened, nodular scars; usually does not affect the face.
- **Acne rosacea** a chronic form of dermatitis of the face in which the middle portion of the face appears red with small red lines caused by dilation of capillaries.
- **Acne vulgaris** an inflammatory eruption of the sebaceous follicles usually occurring on the face, upper back, and chest that consists of blackheads, cysts, papules, and pustules.
- **Noninflammatory acne** open comedones caused by the enlargement and dilation of a plug resulting from the accumulation of oil and dead skin cells inside the hair follicle and by closed comedones that form if the hair follicle pore remains closed; they appear as a tiny, sometimes pink bump in the skin.

Acquired immunodeficiency syndrome (AIDS) see Immune deficiency.

Acquired sideroblastic anemia see Anemia.

ACTH deficiency a condition characterized by decreased or absent production of adrenocorticotropic hormone (ACTH) by the pituitary gland, resulting in a reduction in the secretion of adrenal hormones and subsequent weight loss, lack of appetite, weakness, nausea, vomiting, and low blood pressure.

Actinic keratosis a condition in which a premalignant small, reddish, rough spot appears on skin chronically exposed to the sun.

Acute chest syndrome a syndrome occurring in association with sickle cell disease defined by a new infiltrate on chest radiograph; associated with one or more new symptoms: fever, cough, sputum production, dyspnea, or hypoxia. It occurs most commonly in the 2- to 4-year-old age group and declines in incidence with age.

Acute colonic pseudo-obstruction (Ogilvie syndrome) a massive dilation of the large bowel that occurs in critically ill patients and immobilized older adults. It is characterized by significant dilation of the cecum and absence of mechanical obstruction, and is related to excessive sympathetic motor input or decreased parasympathetic motor input.

Acute confusional state (ACS) a form of delirium caused by interference with the metabolic or other biochemical processes essential for normal brain functioning. Symptoms may include disturbances in cognition and levels of awareness, short-term memory deficit, retrograde and anterograde amnesia, and disturbances in orientation, accompanied by restlessness, apprehension, irritability, and apathy. The condition may be associated with an acute physiologic state, delirium, toxic psychosis, or acute brain syndrome.

Acute coronary syndrome a classification encompassing clinical presentations ranging from unstable angina through infarction.

Acute cystitis an inflammation of the bladder, which is the most common site of urinary tract infection.

Acute epiglottitis an infection that causes inflammation of the epiglottis and surrounding tissues and may lead to upper airway blockage.

Acute gastritis an inflammatory disorder of the gastric mucosa, usually caused by injury of the protective mucosal barrier by drugs, chemicals, or *Helicobacter pylori* infection.

Acute glomerulonephritis see Glomerulonephritis.

Acute gouty arthritis an abrupt pain of a joint, most often the great toe, which is swollen, hot, and shiny secondary to an attack of gout.

Acute idiopathic thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Acute leukemia see Leukemia.

Acute liver failure (fulminant liver failure) a rare clinical syndrome resulting from severe impairment or necrosis of liver cells without pre-existing liver disease or cirrhosis. Acetaminophen overdose is the leading cause.

Acute lung injury (ALI)/acute respiratory distress syndrome (ARDS) a spectrum of acute lung inflammations and diffuse alveolocapillary injury.

Acute lymphoblastic leukemia (ALL) see Leukemia.

Acute mesenteric ischemia caused by acute occlusion of the mesenteric artery that results in a significant reduction in mucosal blood flow to the large and small intestines. Aortic aneurysms, arterial thrombi, or emboli can be causes.

Acute mountain sickness (AMS) the presence of a combination of nonspecific symptoms that appear within a few hours after ascent to altitude, and may include headache, loss of appetite, nausea, vomiting, weakness, lassitude, dizziness, and difficulty sleeping.

Acute myelogenous leukemia (AML) see Leukemia.

Acute otitis media (AOM) an infection of the middle ear space, behind the eardrum (tympanic membrane); characterized by pain, dizziness, and partial loss of hearing.

Acute orthostatic hypotension an abnormal decrease in blood pressure when a person stands. This may lead to fainting.

Acute pancreatitis inflammation of the pancreas resulting from obstruction to the outflow of pancreatic digestive enzymes caused by bile duct or pancreatic duct obstruction (e.g., gallstones). Usually a mild disease and resolves spontaneously.

Acute poststreptococcal glomerulonephritis (PSGN) see Glomerulonephritis.

Acute pyelonephritis acute inflammation of the renal parenchyma and pelvis characterized by small cortical abscesses and yellowish streaks in the medulla resulting from the accumulation of pus in the collecting tubules and interstitial tissue.

Acute renal failure (acute renal injury) a sudden decline in kidney function with a decrease in glomerular filtration and accumulation of nitrogenous waste products in the blood as demonstrated by an elevation in plasma creatinine and blood urea nitrogen levels.

Acute respiratory distress syndrome (ARDS) capillaries or alveoli of the lungs are damaged as a result of infection, injury, blood loss, or inhalation injury causing fluid to leak from the capillaries into the alveoli, resulting in pulmonary edema and collapse of some alveoli.

Acute tubular necrosis (ATN) the kidney undergoes ischemic or nephrotoxic injury because of severe hypotension, aminoglycosides, or radiocontrast agents and produces granular and epithelial cell casts in urine.

Acute urethral syndrome the bladder is irritated and the typical symptoms of a urinary tract infection are present in the absence of an infection.

Adenocarcinoma tumor arising from epithelial cells with a glandular or glandlike pattern.

Adenocystic tumor (cylindroma) rare bronchial gland tumors that arise predominantly in the trachea or large airways and cause obstruction.

Adenomyosis the presence of islands of endometrial glands surrounded by benign endometrial stroma within the uterine myometrium.

Adenosine deaminase (ADA) deficiency see Immune deficiency.

Adrenarche growth of axillary and pubic hair and other physiologic changes induced by hyperactivity of the suprarenal cortex and adrenocortical secretion of androgenic hormones in early puberty.

Agammaglobulinemia see Immune deficiency.

Ageusia loss of the sense of taste.

Agoraphobia a mental disorder characterized by an irrational fear of leaving the familiar setting of home, or venturing into the open, so pervasive that a large number of external life situations are entered into reluctantly or are avoided; often associated with panic attacks.

Agranulocytosis see Immune deficiency.

Akinesia slowness or loss of normal motor function resulting in impaired muscle movement.

Akinetic mutism (AM) a syndrome characterized by the inability to speak, loss of voluntary movement, and apparent loss of emotional feeling. It is related to lesions of the upper brainstem.

Albright syndrome (Albright-McCune-Sternberg syndrome) polyostotic fibrous dysplasia, patchy dermal pigmentation, and endocrine dysfunction.

Alcoholic cirrhosis see Cirrhosis.

Alcoholic fatty liver (steatosis) the mildest form of alcoholic liver disease; can be caused by chronic ingestion of relatively small amounts of alcohol, may be asymptomatic, and is reversible with cessation of drinking.

Alcoholic hepatitis (steatohepatitis) a precursor of cirrhosis characterized by inflammation; degeneration and necrosis of hepatocytes; infiltration of neutrophils, macrophages, and lymphocytes; immunologic alterations; and lipid peroxidation.

Algor mortis postmortem reduction of body temperature.

Alkaline reflux gastritis inflammation of the stomach caused by reflux of bile and alkaline pancreatic secretions that contain proteolytic enzymes and disrupt the mucosal barrier in the remnant stomach.

Allergic contact dermatitis contact dermatitis attributable to allergic sensitization.

Allodynia a condition in which pain arises from a stimulus that would not normally be experienced as painful.

Allostasis long-term or chronic exaggerated responses to stress.

Alogia inability to speak because of mental deficiency, mental confusion, or aphasia.

Alopecia loss of hair.

Alopecia areata an autoimmune T-cell–mediated chronic inflammatory disease directed at hair follicles that results in baldness, usually in round patches.

Alpha-thalassemia major see Anemia.

Alpha-thalassemia minor see Anemia.

Alzheimer disease (dementia of Alzheimer type [DAT], senile disease complex) a degenerative disease characterized by amyloid plaques and fibrillary tangles in the cortex and atrophy and widened sulci in the frontal and temporal lobes.

Amblyopia poor vision caused by abnormal development of visual areas of the brain in response to abnormal visual stimulation during early development.

Amyotrophic lateral sclerosis (ALS) (sporadic motor system disease, sporadic motor neuron disease, motor neuron disease, Lou Gehrig disease) a disease that breaks down tissues in the nervous system (a neurodegenerative disease); it is of unknown cause and affects the nerves responsible for movement.

Anaphylactic shock a state of shock caused by a severe allergic reaction that lowers blood pressure and results in urticaria, breathing difficulties, and possibly death.

Anaphylactoid purpura (allergic purpura, Henoch-Schönlein purpura) nonthrombocytopenic purpura attributable to immune hypersensitivity to foods, drugs, and insect bites.

Anemia hemoglobin concentration is less than normal because of a deficiency in red blood cells, a low level of hemoglobin in cells, or both; it manifests as pallor of the skin and mucous membranes, weakness, dizziness, easy fatigability, and drowsiness caused by oxygen deficiency.

- **Congenital hemolytic anemias**
  - **Alpha-thalassemia major** thalassemia in which all four α-chains of hemoglobin are defective, resulting in a fatal condition because oxygen cannot be released to the tissues.
  - **Alpha-thalassemia minor** thalassemia in which two α-chains of hemoglobin are defective.
  - **Beta-thalassemia major (Cooley anemia)** thalassemia in which α-chain synthesis and β-chain synthesis are uncoupled; β-chain production is depressed moderately in the heterozygous form, **beta-thalassemia minor,** and severely in the homozygous form, **beta-thalassemia major,** resulting in erythrocytes that have a reduced amount of hemoglobin and accumulations of free α-chains.
  - **Beta-thalassemia minor** see above.
  - **Glucose-6-phosphate dehydrogenase (G6PD) deficiency** an inherited condition that is asymptomatic in the absence of exposure to particular substances such as certain medicines, mothballs, or severe infections; with exposure the red blood cells undergo destruction, producing excessive bilirubin that overloads the liver and causes jaundice.
  - **Hemoglobin H disease** a form of alpha-thalassemia in which a hemoglobin H gene is expressed but cannot bind oxygen.
  - **Hereditary spherocytosis (congenital hemolytic anemia, congenital acholuric jaundice)** a defect in the cell membrane of red blood cells that causes thickened, fragile red blood cells that are susceptible to spontaneous hemolysis and results in chronic anemia, jaundice, fever, and abdominal pain.
  - **Sickle cell anemia (sickle cell disease [SCD])** an inherited autosomal recessive disorder of the blood caused by abnormal hemoglobin that distorts red blood cells and makes them fragile and prone to rupture and can cause anemia, joint pain, fever, leg ulcers, and jaundice.
  - **Sickle cell–Hb C disease** a heterozygous form in which the child simultaneously inherits a hemoglobin C gene from another parent.
  - **Sickle cell–thalassemia disease** a heterozygous form in which the child simultaneously inherits a thalassemia gene from another parent.
  - **Sickle cell trait** an inherited condition in which an individual carries only one gene for sickle cell disease and is without symptoms.
  - **Thalassemia** a potentially fatal genetic disorder in which hemoglobin molecules are abnormal, resulting in severe anemia; enlarged heart, liver, and spleen; and skeletal deformation.
- **Macrocytic anemia (megaloblastic anemia)** a condition characterized by erythrocytes that are larger than normal; associated with deficiency of vitamin B_{12} or folic acid caused by inadequate intake or insufficient absorption secondary to alcoholism or drugs that inhibit DNA replication.
  - **Pernicious anemia** an autoimmune disorder that causes a deficiency in intrinsic factor, resulting in the inability to absorb vitamin B_{12} and a subsequent increase in the production of abnormal erythrocytes.
- **Microcytic-hypochromic anemia** a condition in which red blood cells are smaller than normal as a result of iron deficiency.
  - **Acquired sideroblastic anemia** a heterogeneous group of disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs as a primary disorder with no known cause (idiopathic) or is associated with other myeloproliferative or myeloplastic disorders.
  - **Hereditary sideroblastic anemia** heterogeneous group of rare disorders characterized by anemia of varying severity caused by a defect in mitochondrial heme synthesis; occurs almost exclusively in males, suggesting a predominant recessive X-linked transmission.
  - **Hypoplastic anemia** a condition in which anemia results from greatly depressed, inadequately functioning bone marrow and smaller-than-normal erythrocytes.
  - **Iron deficiency anemia (IDA)** an insufficient dietary intake or absorption of iron, resulting in decreased incorporation of hemoglobin into red blood cells and subsequent feelings of fatigue, weakness, and shortness of breath as well as pale earlobes, palms, and conjunctivae.
  - **Reversible sideroblastic anemia** associated with alcoholism; results from nutritional deficiencies of folate.
  - **Sideroblastic anemia (SA)** refractory anemia of varying severity that is caused by altered mitochondrial metabolism and is marked by sideroblasts in the bone marrow.
- **Normocytic-normochromic anemia (NNA)** erythrocytes are of normal size and hemoglobin content but of insufficient number; usually caused by hereditary spherocytosis, drug-induced anemia, and anemia secondary to malignancies.
  - **Anemia of chronic disease (ACD)** a mild to moderate anemia resulting from decreased erythropoiesis in individuals with conditions of chronic systemic disease or inflammation.
  - **Aplastic anemia** decreased bone marrow production of adequate amounts of new red blood cells; results from an

autoimmune disorder or exposure to radiation or substances such as benzene or certain drugs.

Aplastic crisis temporary loss of bone marrow causes erythropoiesis, resulting in an acute fall in hemoglobin levels and subsequent anemia.

Autoimmune hemolytic anemia (AIHA) a form of hemolytic anemia involving autoantibodies against red blood cell antigens.

Cold agglutinin autoimmune hemolytic anemia acquired disorder caused by autoantibodies against antigens normally on the surface of erythrocytes; mediated by immunoglobulin M (IgM) antibodies that optimally bind to and agglutinate erythrocytes in colder portions of the body (e.g., fingers, toes), and occurs less often than warm antibody hemolysis, affecting mostly middle-aged and older adults.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) a disorder in which exposure to cold initiates acute and severe intravascular hemolysis that, unlike cold agglutinin anemia, results in hemoglobinuria. The chronic form of this anemia is extremely rare, but an acute form of paroxysmal cold hemoglobinuria is frequently observed in autoimmune hemolytic anemia of childhood.

Drug-induced hemolytic anemia a form of immune hemolytic anemia usually resulting from an allergic reaction against foreign antigens (e.g., antibiotics) that have attached to the surface of red blood cells.

Fanconi anemia a genetic disease affecting bone marrow that is characterized by pancytopenia, hypoplasia of the bone marrow, congenital anomalies, and pigment changes of the skin and that predisposes the individual to myelodysplasia and to acute myeloid leukemia or cancers of the mouth, esophagus, intestinal and urinary tracts, and reproductive organs.

Hemolytic anemia a condition in which red blood cells are destroyed in response to certain toxic or infectious agents or in certain inherited blood disorders and the rate of breakdown exceeds the body's ability to compensate.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) a condition that affects a fetus or newborn in which red blood cells break down because of antibodies made by the mother that are directed against the infant's red cells, potentially resulting in anemia, heart failure, jaundice, and brain damage.

Posthemorrhagic anemia a type of normocytic-normochromic anemia that is caused by sudden blood loss in an individual with normal iron stores and triggers a compensatory response in which water and electrolytes from tissues and interstitial spaces are used to expand plasma volume and accelerate the formation and development of blood cells.

Warm autoimmune hemolytic anemia the most common form of autoimmune hemolytic anemia; caused by IgG that binds to erythrocytes at normal body temperature; often secondary to other diseases, especially lymphomas, chronic lymphocytic leukemia, other neoplastic disorders, or systemic lupus erythematosus (SLE).

Anencephaly anomaly in which the soft, bony component of the skull and much of the brain are missing.

Angelman syndrome (happy puppet syndrome) an inherited syndrome of jerky puppetlike movements, frequent laughter, mental and motor retardation, peculiar open-mouthed facies, and seizures.

Angina pectoris chest pain caused by reduced cardiac blood flow and myocardial ischemia.

Anhedonia absence of pleasure from the performance of acts that would ordinarily be pleasurable.

Ankylosing spondylitis (AS, spondyloarthritis) chronic inflammation of the spine and sacroiliac joints with gradual fusion of the vertebrae that immobilizes the spine.

Anorexia nervosa (AN) a disorder with both psychologic and physiologic components that begins with dieting to lose weight and manifests into an inappropriate self-control behavior; continued restrictive eating may lead to starvation and eventually death.

Anorgasmia (orgasmic dysfunction) the inability of the woman to reach or achieve orgasm.

Anuria urine output less than 50 ml/day.

Anxiety disorder a group of disorders involving various manifestations of anxiety that are grouped together and include panic disorder, specific phobia, social phobia, obsessive-compulsive disorder (OCD), posttraumatic stress disorder (PTSD), acute stress disorder, generalized anxiety disorder (GAD), and anxiety disorders secondary to medical conditions or substance-induced or not otherwise specified.

Aplastic anemia see Anemia.

Aplastic crisis see Anemia.

Appendicitis inflammation of the appendix as a result of blockage of the opening from the appendix into the cecum; the appendix wall becomes infected and ruptures, allowing the infection to spread throughout the abdomen and cause pain, anorexia, fever, nausea, vomiting, and diarrhea.

Apraxia a disorder of voluntary movement consisting of impairment of the performance of skilled or purposeful movements; results from acquired cerebral disease.

Arcus senilis a gray to white ring at the periphery of the cornea; caused by deposits of cholesterol in the cornea or hyaline degeneration and occurs primarily in older persons.

Areflexia absence of reflexes.

Arterial ischemic stroke (pediatric arterial ischemic stroke) a rare disorder in children resulting from embolism, arteriopathy, or, rarely, sinovenous thrombosis and leading to a decreased flow of blood and oxygen to areas of the brain.

Asbestosis pulmonary inflammation and fibrosis resulting from inhalation of hydrous silicates of various metals in fibrous form.

Aseptic meningitis a form of inflammation of the meninges and subarachnoid space surrounding the brain and spinal cord without evidence of bacterial infection; may be associated with viral infection, systemic disease, or drugs.

Aspiration pneumonitis a condition caused by the abnormal entry of fluids, particulate matter, or secretions into the lower airways that can lead to chemical pneumonitis from entry of toxic material such as gastric acid, from bacterial infection, or by mechanical obstruction of the lower airways.

Asthma a chronic inflammatory disorder of the airways involving bronchial hyperresponsiveness and airway obstruction marked by periodic attacks of wheezing, shortness of breath, a tight feeling in the chest, and a cough that produces mucus because of an allergic reaction triggered by certain drugs, irritants, viral infection, exercise, or emotional stress.

Asymptomatic bacteriuria the presence of bacteria in the urine without evidence of infection.

Ataxia-telangiectasia (AT) see Immune deficiency.

Ataxic cerebral palsy a form of cerebral palsy associated with damage to the cerebellum and resulting in gait disturbances and instability; at birth the infant may have hypotonia, but develops stiffness of the trunk muscles later in infancy.

Atelectasis a part of or an entire lung collapses and the alveoli deflate as a result of surgery, smoking, or blockage of a bronchiole.

Absorption atelectasis collapse of lung tissue resulting from gradual absorption of air from obstructed or hypoventilated alveoli or from inhalation of concentrated oxygen or anesthetic agents.

Compression atelectasis air pressure in the pleural space pushes against the already recoiled lung, causing compression atelectasis, and against the mediastinum, compressing and displacing the heart and great vessels.

Surfactant impairment decreased production or inactivation of surfactant, which is necessary to reduce surface tension in the alveoli and causes lung collapse during expiration; can occur because of premature birth, acute respiratory distress syndrome, anesthesia, or mechanical ventilation.

Atherosclerosis a type of arteriosclerosis in which the inflammatory changes of thickening and hardening of the walls of large- and medium-sized arteries are caused by an atheroma or plaque of lipids, cells, and connective tissue in the tunica intima.

Atopic dermatitis (AD) (allergic dermatitis) a chronic hereditary skin disease characterized by intense itching and inflamed skin that causes redness, swelling, cracking, crusting, and scaling.

Atrial septal defect (ASD) a congenital heart disease involving the interatrial septum of the heart that separates the right and left atria, which results in misdirected blood flow between the two sides of the heart.

Atrioventricular canal (AVC) defect a large hole is present in the center of the heart where the wall between the atria joins the wall between the ventricles, and the tricuspid and mitral valves are formed into a single large valve that crosses the defect.

Atypical ductal hyperplasia (ADH) abnormal proliferating cells in breast ducts.

Atypical hyperplasia increased number of cells with some variation in cellular structure but without sufficient qualitative or quantitative features of carcinoma.

Atypical lobular hyperplasia (ALH) abnormal proliferating cells in breast lobules.

Autoimmune hemolytic anemia (AIHA) see Anemia.

Autoimmune neonatal thrombocytopenia see Thrombocytopenia.

Autoimmune vascular purpura (allergic purpura) purpura caused by antibody-mediated injury of blood vessel walls, typically arterioles and capillaries. The reaction is directed to foreign proteins or chemicals in the blood (microorganisms, drugs, or other chemicals) that deposit on the vessel walls.

Autonomic hyperreflexia (dysreflexia) a syndrome resulting from afferent stimuli that cause intense sympathetic discharge originating with spinal cord injury above the major splanchnic outflow; characterized by hypertension, bradycardia, sweating of the forehead, severe headache, and piloerection on distention of the bladder and rectum.

Autosomal agammaglobulinemia see Immune deficiency.

Autosomal dominant polycystic kidney disease (ADPKD) a progressive disease characterized by formation of multiple cysts of varying size scattered diffusely throughout both kidneys, resulting in compression and destruction of renal parenchyma, usually with hypertension, gross hematuria, and uremia leading to progressive renal failure.

Autosomal hyper-IgM syndrome see Immune deficiency.

Azotemia kidney dysfunction characterized by increased serum urea levels and frequently associated with increased creatinine levels.

Bacterial pneumonia an acute or chronic disease marked by inflammation of the lungs caused by bacterial infection.

Bacterial tracheitis a condition in which the larynx, trachea, and bronchi are inflamed and present with signs similar to those of epiglottitis and croup; may result in airway obstruction secondary to subglottic edema or sloughing of the epithelial lining or the mucopurulent membrane within the trachea.

Bacterial vaginosis (BV) a condition caused by an overgrowth of normal vaginal bacteria, causing vaginal discharge with a foul odor.

Balanitis inflammation of the glans penis caused by irritation by environmental substances, physical trauma, or infection.

Bare lymphocyte syndrome see Immune deficiency.

Barrett esophagus chronic peptic ulceration of the esophagus; formation of precancerous lesions with possible progression to adenocarcinoma.

Bartholinitis (Bartholin cyst) inflammation of one or both of the ducts that lead from the introitus (vaginal opening) to the Bartholin/greater vestibular glands.

Basal cell carcinoma a surface epithelial tumor of the skin originating from undifferentiated basal or germinative cells.

B-cell neoplasm see Lymphoma.

Becker muscular dystrophy a general term for a number of late-onset X-linked recessive hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Beckwith-Wiedemann syndrome an inherited disorder characterized by exomphalos, macroglossia, and gigantism; often associated with visceromegaly, adrenocortical cytomegaly, and dysplasia of the renal medulla.

Benign breast disease (BBD) a spectrum of noncancerous changes in ducts and lobules of the breast, including irregular lumps, cysts, sensitive nipples, and itching.

Benign prostatic hyperplasia (BPH) enlargement of the prostate gland, which may press against the urethra and bladder, interfering with urine flow.

Beta-thalassemia major (Cooley anemia) see Anemia.

Beta-thalassemia minor see Anemia.

Biliary atresia a condition in newborn children in which the biliary tract is blocked or absent, causing bile accumulation and progressive liver failure.

Biliary cirrhosis see Cirrhosis.

Bipolar disorder psychiatric disorder characterized by alternating mania or hypomania and depression, often with periods of normal mood in between, and changes in energy and behavior according to mood.

Blast injury tissue damage from compressive waves of air against the body followed by waves of decreased pressure.

Blepharitis inflammation of the eyelids.

B-lymphocyte deficiency see Immune deficiency.

Bradykinesia decreased spontaneity and movement; a feature of extrapyramidal disorders, such as Parkinson disease.

Brainstem gliomas a group of tumors located in the brainstem that are usually classified as high grade and result in the sudden onset of symptoms including headaches, vomiting, and visual disturbances.

Bronchial carcinoid tumor an obstructing tumor of the trachea or large bronchi that may cause paraneoplastic symptoms.

Bronchiectasis dilation of the bronchi in response to obstruction, necrotizing pneumonias, cystic fibrosis, or Kartagener syndrome (a hereditary syndrome consisting of dextrocardia, bronchiectasis, and sinusitis).

Bronchiolitis inflammation of the bronchioles usually caused by viral infection.

Bronchiolitis obliterans partial or complete obliteration of bronchioles and some bronchi by granulation and fibrotic tissue masses.

Bronchiolitis obliterans with organizing pneumonia (BOOP) obstruction of the bronchioles and alveolar ducts by fibrous granulation tissue that is further complicated by the development of pneumonia.

Bronchopulmonary dysplasia (BPD) a condition most often found in premature infants in which chronic pulmonary insufficiency occurs because of long-term artificial pulmonary ventilation.

Bruton's agammaglobulinemia see Immune deficiency.

Bulbar palsy a form of palsy resulting from impaired function of the cranial nerves from degeneration of the motor neurons of primarily the brainstem; manifested as weakness and wasting of the various bulbar muscles, resulting in difficulty articulating words (dysarthria) and difficulty swallowing (dysphagia); fluid regurgitation is a major symptom and can cause aspiration.

Bullous pemphigoid (BP) a more benign autoimmune disease than pemphigus vulgaris, with blistering of the subepidermal skin layer.

Burkitt lymphoma see Lymphoma.

Burn shock a phenomenon consisting of both a hypovolemic cardiovascular component and a cellular component; results from massive fluid losses from the circulating blood volume.

C1 deficiency see Immune deficiency.

C2 deficiency see Immune deficiency.

C3 deficiency see Immune deficiency.

C3 receptor deficiency see Immune deficiency.

C4 deficiency see Immune deficiency.

C9 deficiency see Immune deficiency.

Cachexia illness and malnutrition seen in individuals with cancer that results in wasting and eventual death.

Calculi or urinary stone (urolithiasis) masses of crystals, protein, or other substances that are a common cause of urinary tract obstruction in adults.

Candidiasis a fungal infection caused by an overgrowth of normal *Candida albicans* found in the skin and mucous membranes of the mouth, respiratory tract, or vagina.

Caplan syndrome formation in coal workers of intrapulmonary nodules in pneumoconiosis that are histologically similar to subcutaneous rheumatoid nodules associated with rheumatoid arthritis.

Carbuncles a condition in which a bacterial infection of the hair follicle or sebaceous gland ducts becomes painful and discharges pus through various openings.

Carcinoma epithelial cell tumor.

Carcinoma in situ (CIS) preinvasive epithelial malignant tumors of glandular or squamous cell origin.

Cardiogenic shock a condition resulting from decreased cardiac output caused by heart disease in which the heart is unable to pump blood through the body, usually because of myocardial infarction.

Cardiomyopathy(ies) a diverse group of diseases primarily affecting the myocardium and

resulting from tissue remodeling caused by myocardial and neurohumoral responses to ischemic and hypertensive alterations.

Cavernous (congenital) hemangioma a birthmark that is similar to the strawberry hemangioma but is more deeply rooted and may appear as a red-blue spongy mass of tissue filled with blood.

Central core disease (CCD) an autosomal dominant congenital myopathy characterized by hypotonia, delay of motor development in infancy, and nonprogressive or slowly progressive muscle weakness; on biopsy the central core of muscle fibers stains abnormally, myofibrils are abnormally compact, and there is virtual absence of mitochondria and sarcoplasmic reticulum; histochemically, the cores are devoid of oxidative enzyme, phosphorylase, and ATPase activity.

Central precocious puberty condition in which puberty begins prematurely with normal changes in the hypothalamopituitary (HPG) axis with premature development of secondary sexual characteristics and premature closure of the epiphysis of long bones, resulting in lifelong short stature.

Centriacinar emphysema see Emphysema.

Cerebellar astrocytoma brain tumor of the right or left cerebellar hemisphere that causes motor symptoms on the same side as the tumor.

Cerebral palsy (CP) a developmental brain injury that occurs before or shortly after birth and causes muscular impairment affecting motor function and also may alter speech and learning abilities.

Cervical dysplasia (cervical intraepithelial neoplasia [CIN]) a condition characterized by the appearance of abnormal cervical cells that are considered precancerous.

Cervicitis inflammation of the mucous membrane of the uterine cervix caused by infection, typically by chlamydia, genital herpes, or gonorrhea.

Chediak-Higashi syndrome see Immune deficiency.

Cheyne-Stokes respiration an abnormal pattern of breathing in which tidal volume gradually increases followed by a gradual decrease and a period of apnea before returning to a normal respiratory pattern.

Chickenpox an infectious viral disease that is spread by direct contact or through the air by coughing or sneezing; it causes a blister-like rash that first affects the face and trunk and then can spread over the rest of the body; symptoms include severe itching, fatigue, and fever.

Childhood absence epilepsy (petit mal seizures, nonconvulsive epilepsy) a type of generalized epilepsy; age of onset is 4 to 10 years.

Chlamydia a sexually transmitted bacterial infection that can cause infertility and blindness.

Choking asphyxiation obstruction of the internal airways.

Cholangiocellular carcinoma (cholangiocarcinoma) primary carcinomas of the liver that develop in the bile ducts.

Cholecystitis inflammation of the gallbladder commonly caused by impaction of a gallstone that causes right upper quadrant pain and possibly a rupture and abscess in the gallbladder.

Cholelithiasis the presence or formation of gallstones in the gallbladder or bile ducts.

Chondrosarcoma a cancer of the cartilage that usually occurs in the pelvic bones, shoulder bones, and the upper part of the arms and legs.

Chronic active hepatitis the persistence of clinical manifestations and liver inflammation after the acute stages with consistently abnormal liver function tests and persistent HBsAg creating a predisposition to cirrhosis and primary hepatocellular carcinoma.

Chronic bronchitis chronic bronchitis, particularly as a cause of chronic cough in smokers.

Chronic gastritis tends to occur in older adults with chronic inflammation, mucosal atrophy, and epithelial metaplasia; may be immune (fundal) or nonimmune (antral), depending on the pathogenesis and location of the lesions.

Chronic glomerulonephritis see Glomerulonephritis.

Chronic granulomatous disease (CGD) see Immune deficiency.

Chronic kidney disease (CKD) progressive loss of renal function associated with systemic diseases such as hypertension, diabetes mellitus, systemic lupus erythematosus, or intrinsic kidney disease, including kidney stones, acute kidney injury, chronic glomerulonephritis, chronic pyelonephritis, obstructive uropathies, or vascular disorders.

Chronic leukemia see Leukemia.

Chronic lymphocytic leukemia (CLL) see Leukemia.

Chronic mesenteric ischemia development of regions of compromised blood flow in the mesenterium secondary to atherosclerosis (most common), congestive heart failure, dysrhythmias, hemorrhage, thrombus formation, aortic aneurysm, or any condition that decreases arterial blood flow. Chronic occlusion is often accompanied by formation of collateral circulation that may be able to nourish the resting intestine.

Chronic mucocutaneous candidiasis see Immune deficiency.

Chronic myelogenous leukemia (CML) see Leukemia.

Chronic obstructive pulmonary disease (COPD) any of a group of irreversible respiratory diseases (chronic bronchitis, emphysema, α_1-antitrypsin deficiency) that are characterized by airflow obstruction or limitation.

Chronic pancreatitis inflammation of the pancreas resulting from repeated exacerbations of acute pancreatitis that lead to chronic changes; associated with obstruction from gallstones, autoimmune disease, gene mutations, smoking, occupational chemical exposure, and obesity.

Chronic pyelonephritis persistent or recurrent infection of the kidney leading to scarring.

Chronic relapsing thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Cirrhosis degeneration of liver tissue resulting in fibrosis with nodule and scar formation that compromises liver function.

Alcoholic cirrhosis destructive inflammation of the liver caused by the toxic effects of alcohol metabolism, immunologic processes, oxidative stress from lipid peroxidation, and malnutrition.

Biliary cirrhosis a form of alcoholic cirrhosis in which damage and inflammation leading to cirrhosis begin in bile canaliculi and bile ducts, rather than in the hepatocytes.

- **Primary biliary cirrhosis** a T-lymphocyte- and antibody-mediated destruction of the small intrahepatic bile ducts.

Cloacal exstrophy family of congenital anomalies with two exstrophied bladder units separated by an exstrophied segment of intestine, which is usually cecum, receiving ileum superiorly and continuing distally to blind ending microcolon.

Coal worker pneumoconiosis (coal miner lung, black lung) mild to severe pneumoconiosis (pulmonary fibrosis) caused by coal dust (coal, silica, quartz) deposits in the lung; symptoms initially present as a productive cough and wheezing, but may advance to chronic bronchitis and emphysema.

Coarctation of the aorta (COA) a condition in which the aorta narrows in the area where the ductus arteriosus inserts; narrowing usually occurs preductal in children and postductal in adults.

Cold agglutinin autoimmune hemolytic anemia see Anemia.

Cold hemolysin autoimmune hemolytic anemia (paroxysmal cold hemoglobinuria) see Anemia.

Combined T- and B-lymphocyte deficiency see Immune deficiency.

Common variable immune deficiency see Immune deficiency.

Communicating (extraventricular) hydrocephalus a disorder in which the cerebrospinal fluid pathways are intact but cerebrospinal fluid absorption is impaired.

Complement deficiency see Immune deficiency.

Complete precocious puberty refers to the early onset and progression of all pubertal features (i.e., thelarche, pubarche, and menarche).

Complex febrile seizure seizures with characteristic features similar to those of simple febrile seizure with a longer duration and focal characteristics; occur more than once in a 24-hour period.

Complex regional pain syndrome (CRPS) diffuse persistent pain usually in an extremity often associated with vasomotor disturbances, trophic changes, and limitation or immobility of joints; frequently follows a local injury.

Compression atelectasis see Atelectasis.

Compressive syndrome (sensorimotor syndrome; crush syndrome) a shocklike state that follows release of a limb or limbs or the trunk and pelvis after a prolonged period of compression, such as by a heavy weight; characterized by suppression of renal function, probably the result of damage to the renal tubules by myoglobin from the damaged muscles.

Congenital adrenal hyperplasia a group of autosomal recessively inherited disorders associated with a deficiency of one of the enzymes

involved in cortisol biosynthesis, resulting in elevation of ACTH levels and overproduction and accumulation of cortisol precursors proximal to the block; androgens are produced in excess, causing virilization. The most common disorder is the 21-hydroxylase deficiency, caused by mutation in the cytochrome P450 21-hydroxylase gene *(CYP21)* on chromosome 6p.

Congenital aganglionic megacolon (Hirschsprung disease) a congenital defect in which the nerves that innervate the anus through the wall of the bowel are absent, resulting in enlargement of the bowel superior to the point where the nerves are missing and a subsequent decrease in peristalsis that results in chronic constipation.

Congenital hydrocephalus excessive accumulation of cerebrospinal fluid present at birth and characterized by increased intracranial pressure (ICP). This increase may be caused by a blockage within the ventricular system in which the CSF flows, an imbalance in the production of CSF, or a reduced reabsorption of CSF that results in ventricular enlargement and increased ICP.

Congenital hypothyroidism lack of secretion of thyroid hormone.

Congenital (infantile) nephrotic syndrome (Finnish type) a very rare form of nephrotic syndrome caused by a defect in a kidney protein resulting in excessive amounts of protein excreted in the urine.

Congestive splenomegaly enlargement of the spleen accompanied by ascites, portal hypertension, and esophageal varices; most commonly seen in those with hepatic cirrhosis.

Consumptive thrombohemorrhagic disorders heterogeneous group of conditions that demonstrate the entire range of hemorrhagic and thrombotic pathologic conditions.

Contact dermatitis an allergic response to an environmental antigen binding to specific carrier proteins contained in an individual's skin.

Contrecoup injury brain injury resulting from the brain hitting the inside of the skull on the side opposite the site of blunt force trauma.

Cor pulmonale right-sided heart failure caused by prolonged pulmonary hypertension.

Coronary artery disease (CAD) narrowing of the lumen of one or more of the coronary arteries, usually attributable to atherosclerosis, leading to myocardial ischemia; can cause congestive heart failure, angina pectoris, or myocardial infarction.

Craniopharyngioma a brain tumor that develops in the pituitary gland and most often affects children, causing headache, seizure, diabetes insipidus, early onset of puberty, and delayed growth.

Craniosynostosis (craniostenosis) (see Syndromic craniosynostosis) premature ossification of the skull and closure of the sutures, resulting in abnormal skull expansion and asymmetric skull growth.

Cri du chat syndrome a hereditary congenital syndrome characterized by hypertelorism, microcephaly, severe mental deficiency, and a plaintive catlike cry; caused by deletion of the short arm of chromosome 5.

Crohn disease (CD) an autoimmune condition in which the intestines and possibly other regions of the digestive system are chronically inflamed and ulcerated, causing chronic diarrhea, disrupted digestion, and subsequent difficulty eating and digesting food.

Croup a viral infection that involves the larynx, trachea, and the airways leading to the lungs and that can result in serious breathing difficulties, hoarseness, sore throat, and a hacking cough.

Cryptorchidism the scrotum of one or both testes is absent because of failure of the testis to descend from the abdominal position during fetal development.

Curling ulcer ischemic ulcers of the stomach and duodenal mucosa that develop within hours after an event, such as hemorrhage, multisystem trauma, severe burns, heart failure, or sepsis.

Cushing disease adrenal hyperplasia caused by an ACTH-secreting basophil adenoma of the pituitary.

Cushing syndrome increased synthesis and secretion of cortisol from a tumor of the adrenal cortex; caused by administration of glucocorticoid drugs or by the presence of an ACTH-secreting tumor of the anterior lobe of the pituitary gland (Cushing disease), resulting in weight gain, glucose intolerance, and muscle wasting.

Cushing ulcer a stress ulcer associated with severe head trauma or brain surgery.

Cyclic neutropenia see Immune deficiency.

Cylindrical bronchiectasis reversible bronchial dilation with symmetrically dilated airways, as can be seen after pneumonia.

Cystic fibrosis (CF) a genetic disorder of the exocrine glands caused by a mutation in the CF transmembrane regulator gene, resulting in impairment in chloride transfer across cell membranes and subsequent chloride and water accumulation in organs and in thickened secretions that block ducts and form cysts.

Cystitis a condition characterized by acute or chronic inflammation of the urinary bladder, usually caused by bacterial infection of the urethra; symptoms include frequent burning urination, blood in the urine, pain in the pubic area, chills and fever, back pain, and nausea. See Painful bladder syndrome/interstitial cystitis (PBS/IC) for further information.

Dandy-Walker malformation congenital defect of midline cerebellar structures and the fourth ventricle in which hydrocephalus is caused by atresia of the foramina of Luschka or Magendie, which normally allow the fourth ventricle to empty into the areas surrounding the brain, leading the ventricular flow of CSF into a "blind pouch."

Dawn phenomenon abrupt increases in fasting levels of plasma glucose between 5 and 9 AM, in the absence of antecedent hypoglycemia; occurs in diabetic patients receiving insulin therapy.

Decompression sickness (DCS) (Caisson disease) gas embolism created when a person under water returns to the surface too quickly, resulting in cellular hypoxia, joint and muscle pain, and tissue necrosis.

Deep venous thrombosis (DVT) a blood clot or thrombus in a deep vein, usually of the leg.

Degenerative disk disease (DDD) intervertebral disk tissue is replaced by fibrocartilage during aging; functional capacity is rarely altered.

Demyelinating polyneuropathy a type of polyneuropathy in which the peripheral nerve myelin is primarily affected; can be familial (Charcot-Marie-Tooth disease, type 1) or acquired (Guillain-Barré syndrome); motor nerve conduction is slowed or blocked.

Dermatitis herpetiformis pruritic chronic dermatitis with successive groups of symmetrical, erythematous, papular, vesicular, eczematous, or bullous lesions, usually associated with asymptomatic gluten-sensitive enteropathy.

Detrusor areflexia a lower motor neuron disorder that results in an underactive, hypotonic, or atonic bladder function with retention of urine and distention.

Detrusor hyperreflexia (uninhibited or reflex bladder) upper motor neuron disorders in which the bladder empties automatically when it becomes full and the external sphincter functions normally.

Developmental dysplasia of the hip (DDH) a condition in which the hip joint of babies or young children is malformed, with the ball being completely out of the socket or the socket being too shallow to support the ball.

Diabetes diseases having in common the triad of symptoms of polyuria, weight loss, and significant glucosuria.

- **Diabetes insipidus** a disease caused by a deficiency in or resistance to antidiuretic hormone that is characterized by excretion of large amounts of dilute urine because of a decrease in water reabsorption in the kidney.
- **Gestational diabetes mellitus (GDM)** carbohydrate intolerance of variable severity with onset during pregnancy.
- **Type 1 diabetes mellitus** a disorder of carbohydrate metabolism characterized by a decrease in insulin production, resulting in hyperglycemia, ketoacidosis, and eventually renal failure and coronary artery disease.
- **Type 2 diabetes mellitus** a condition of glucose intolerance that normally appears first in adulthood and is exacerbated by obesity and an inactive lifestyle.

Diabetic nephropathy a progressive kidney disease caused by diabetes-induced angiopathy of capillaries in the glomeruli that causes nodular glomerulosclerosis.

Diabetic neuropathy combined sensory and motor disorder often seen in older diabetic patients as a result of microvascular injury involving small blood vessels that supply nerves.

Diabetic retinopathy damage to the retina caused by an overaccumulation of glucose or fructose that damages the blood vessels in the retina; in advanced stages, lack of oxygen in the retina causes fragile blood vessels to grow along the retina and in the vitreous fluid of the eye that may bleed and cause blurred vision.

Diaper dermatitis a type of dermatitis characterized by inflammation of the skin in the diaper

area in infants caused by exposure of the skin to feces and urine.

Diastolic heart failure a condition in which heart contractions are normal but the ventricle does not relax completely; therefore, less blood enters the heart.

Diffuse brain injury (diffuse axonal injury) injury to neuronal axons in many areas of the brain caused by stretching and shearing forces received during brain injury.

DiGeorge syndrome see Immune deficiency.

Dilated cardiomyopathy (congestive cardiomyopathy) a condition in which all four chambers of the heart are enlarged and weakened, resulting in progressive congestive heart failure and the need for heart transplantation.

Discoid (cutaneous) lupus erythematosus (DLE) see Lupus erythematosus.

Disorders of desire (hypoactive sexual desire, decreased libido) the most common sexual dysfunction in women; prevalence increases with age and may be a biologic manifestation of depression, alcohol or other substance abuse, prolactin-secreting pituitary tumors, or testosterone deficiency.

Distal intestinal obstruction syndrome (DIOS) a syndrome seen in cystic fibrosis secondary to impaction with feces and inspissated mucus.

Diverticulitis inflammation of the herniations or saclike outpouchings of mucosa through the muscle layers of the colon wall.

Diverticulosis presence of multiple bulging sacs pushing outward from the wall of the large intestine that may become infected and rupture, causing abdominal pain, tenderness, and fever.

Down syndrome trisomy or translocation of chromosome 21, resulting in mental retardation; distinctive facial appearance with a low nasal bridge, epicanthal folds, protruding tongue, and flat, low-set ears; poor muscle tone (hypotonia); and short stature. Congenital heart defects, reduced ability to resist respiratory tract infections, and increased risk for leukemia are common.

Drug-induced hemolytic anemia see Anemia.

Duchenne muscular dystrophy an X-linked genetic disorder in which fat and fibrous tissue infiltrate and weaken muscle tissues such as in the legs and pelvis, lungs, and heart; usually results in death before adulthood.

Dumping syndrome rapid emptying of hypertonic chyme from a surgically created residual stomach causing nausea, vomiting, bleeding, and diarrhea about 20 minutes after a meal.

Duodenal ulcer most common type of peptic ulcers; usually associated with altered mucosal defenses, rapid gastric emptying, elevated serum gastrin levels, or acid production stimulated by smoking.

Dysfunctional uterine bleeding (DUB) heavy or irregular bleeding in the absence of organic disease, such as submucous fibroids, endometrial polyps, blood dyscrasias, pregnancy, infection, or systemic disease.

Dyskinetic cerebral palsy extreme difficulty in fine motor coordination and purposeful movements resulting from injury to the basal ganglia or thalamus.

Dysphoric mood mood of general dissatisfaction, restlessness, depression, and anxiety; a feeling of unpleasantness or discomfort.

Dysplasia (atypical hyperplasia) abnormal changes in the size, shape, and organization of mature cells; considered a form of atypical hyperplasia.

Dyssynergia development of lesions in the upper motor neurons of the brain and spinal cord; results in loss of coordinated neuromuscular contraction and overactive or hyperreflexive bladder function.

Eczema most common inflammatory disorder of the skin; generally characterized by pruritus, lesions with indistinct borders, and epidermal changes.

Eisenmenger syndrome a progressively developing condition in which a congenital heart defect such as ventricular septal defect is left untreated and causes a reversed right-to-left shunt secondary to increased pressures on the right side of the heart because of pulmonary hypertension.

Embryonic tumor a tumor originating in the gestational period that contains predominantly immature blast cells that cannot differentiate into mature functional cells.

Emphysema pulmonary inflammation resulting in increased work of breathing or physiologic dead space and abnormal permanent enlargement of gas-exchange airways (acini) accompanied by destruction of alveolar walls without obvious fibrosis.

- **Centriacinar emphysema** diminished pulmonary function resulting from septal destruction in the respiratory bronchioles and alveolar ducts, usually in the upper lobes of the lung.
- **Panacinar emphysema** involves destruction of the entire acinus, with damage more randomly distributed and involving the lower lobes of the lung. It tends to occur in older adults and in those with α_1-antitrypsin deficiency.

Empyema (infected pleural effusion) a condition in which purulent fluid is persistently discharged into the pleural space as a result of complications of bacterial infections.

Encephalitis inflammation of the brain usually caused by a virus.

Endometriosis a condition that is common in women of reproductive age in which the tissue lining the uterus is found outside of the uterus, resulting in pain and infertility.

End-stage kidney disease (ESKD) significant loss of renal function; usually less than 10% of renal function remains.

Eosinophilic esophagitis rare, idiopathic inflammatory disease of the esophagus characterized by infiltration of eosinophils associated with atopic disease, including asthma and food allergies.

Ependymoma intracranial tumor that is most commonly found in children and typically arises from the inner lining of the fourth ventricle and the spinal canal.

Epididymitis a painful condition in which the epididymis becomes inflamed, usually as a result of a secondary bacterial infection that is triggered by a variety of underlying conditions such as urinary tract or sexually transmitted infections.

Epilepsy a group of chronic neurologic disorders with paroxysmal brain dysfunction from excessive neuronal discharge; symptoms vary widely from complex behavioral abnormalities to focal convulsions, to momentary spells of impaired consciousness.

Epispadias a birth defect in which the urethra opens on the upper penile surface.

Erysipelas a highly contagious bacterial infection that produces shiny, red swollen areas and fever and can lead to blood poisoning and pneumonia.

Erythema multiforme a skin disease that is caused by allergies, seasonal changes, or drug sensitivities, resulting in the formation of red macules, papules, or subdermal vesicles on the skin and mucous membranes.

Erythema toxicum neonatorum a temporary eruption of redness of the skin, small papules, and occasionally pustules in newborns that is associated with contact dermatitis or hypersensitivity to milk or other allergens.

Erythrodermic (exfoliative) psoriasis see Psoriasis.

Erythromyalgia chronic disorder characterized by warmth, pain, and redness, occurring primarily in the feet and lower legs.

Essential (primary) thrombocythemia (ET) excessive production of platelets (platelet count greater than 400,000/mm^3 of blood); may be primary or secondary (reactive) and is usually asymptomatic until the count exceeds 1 million/mm^3 of blood when intravascular clot formation (thrombosis), hemorrhage, or other abnormalities can occur.

Ewing sarcoma a malignant neoplasm of bone, primarily those of the extremities, including the shoulder girdle, with a predilection for the metaphysis; histologically presents as conspicuous foci of necrosis in association with irregular masses of small, regular, rounded, or ovoid cells.

Exstrophy of the bladder a congenital defect in which the lower abdominal wall is malformed and ruptures.

Extrapyramidal/nonspecific cerebral palsy any of a group of clinical disorders considered to be due to malfunction in the extrapyramidal system and marked by abnormal involuntary movements; included are parkinsonism, athetosis, and chorea.

Facioscapulohumeral muscular dystrophy (FSHD) an autosomal dominant genetic disorder that begins in childhood and causes muscle wasting and weakness, primarily in the face, shoulder, and arms.

Factor H deficiency see Immune deficiency.

Factor I deficiency see Immune deficiency.

Fanconi anemia see Anemia.

Fetal alcohol syndrome (FAS) a syndrome of altered prenatal growth and morphogenesis that occurs in infants born to women who were chronically alcoholic during pregnancy; it includes maxillary hypoplasia, prominence of the forehead and mandible, short palpebral

fissures, microphthalmia, epicanthal folds, severe growth retardation, mental retardation, and microcephaly.

Fibromyalgia muscles, tendons, and joints are painful, stiff, and tender; often accompanied by restless sleep, fatigue, anxiety, depression, and disturbances in bowel function.

Fibrosarcoma a malignant tumor of fibrous connective tissue that usually is derived from immature proliferating fibroblasts.

Fibrous dysplasia (FD) a genetic disorder in which tumor-like growths or lesions form in one or more bones and replace the medullary bone with fibrous tissue, resulting in expansion and weakening of the bone.

Florid hyperplasia rapid and unexpected cell growth in the lining of the breast ducts.

Focal segmental glomerulosclerosis (FSGS) a condition in which glomerular capillaries with thickened basement membranes and increased mesangial matrix collapse in segments. Usually presents as nephrotic syndrome.

Frontotemporal dementia (FTD) (Pick disease) progressive circumscribed cerebral atrophy; a rare type of cerebrodegenerative disorder manifested primarily as dementia, in which there is striking atrophy of portions of the frontal and temporal lobes.

FSH deficiency a condition characterized by decreased or absent production of follicle-stimulating hormone (FSH), resulting in a decline in spermatogenesis/oogenesis and associated infertility.

Furuncles staphylococcal infection produces painful pus-filled inflamed hair follicles and involves surrounding skin and subcutaneous tissue.

Fusiform aneurysm (giant aneurysm) large aneurysm that stretches to affect the entire circumference of the arterial wall.

Galactorrhea (inappropriate lactation) a condition in which milk-like fluid is secreted from the breast because of hormonal alterations that are not associated with childbirth or nursing.

Ganglioneuroblastoma an embryonal aggressive tumor of intermediate cellular differentiation that originates outside the CNS in the developing sympathetic nervous system.

Ganglioneuroma a benign neoplasm composed of mature ganglionic neurons scattered within a stroma of neurofibrils and collagenous fibers.

Gangliosidosis any disease characterized by abnormal accumulation of specific gangliosides within the nervous system (e.g., Tay-Sachs disease).

Gastroesophageal reflux disease (GERD) the reflux of acid and pepsin from the stomach to the esophagus that causes esophagitis.

General adaptation syndrome (GAS) the sum of all nonspecific reactions of the body to prolonged systemic stress, comprising alarm, resistance, and exhaustion.

Generalized anxiety disorder (GAD) an anxiety disorder characterized by an excessively anxious mood lasting at least 1 month that interferes with daily functioning and may be accompanied by jitteriness, sweating, feelings of catastrophe concerning one's family or self, and irritability.

Generalized neuropathy a functional disturbance or pathologic change in the cell body of one type of peripheral neuron.

Genital herpes a sexually transmitted viral infection that is caused primarily by herpes simplex virus type 2 and is characterized by painful lesions in the genital and anal regions.

Gestational diabetes mellitus (GDM) see Diabetes.

GH deficiency a condition characterized by decreased or absent production of growth hormone (GH), resulting in a decline in insulin-like growth factor 1 and dwarfism if the deficiency is prepubertal.

Glaucoma a disease of the eye characterized by increased intraocular pressure, excavation, and atrophy of the optic nerve; produces defects in the field of vision and eventual blindness.

Glomerulonephritis inflammation of the renal glomeruli that may not produce symptoms or may present with hematuria and proteinuria.

- **Acute glomerulonephritis** an inflammatory disease of both kidneys predominantly affecting children from ages 2 to 12.
- **Acute poststreptococcal glomerulonephritis (PSGN)** kidney disease secondary to infection with *Streptococci* in which bacterial antigens complex with antibodies in the blood, deposit in the kidneys, and initiate an immune complex–mediated hypersensitivity reaction.
- **Chronic glomerulonephritis** a slowly progressive glomerulonephritis most often associated with other systemic disease, including diabetes, malaria, hepatitis, or systemic lupus erythematosus, that generally leads to irreversible renal failure.
- **Membranoproliferative glomerulonephritis (MPGN)** a chronic, slowly progressive glomerulonephritis in which the glomeruli are enlarged as a result of proliferation of mesangial cells and irregular thickening of the capillary walls, which narrows the capillary lumina.
- **Membranous glomerulonephritis** a slowly progressive disease of unknown origin or that occurs secondary to autoimmune conditions, infections, specific drugs, or malignant tumors that is caused by immune complexes formed from the binding of antibodies to antigens of the glomerular basement membrane (GBM) or antigens transported from the systemic circulation and implanted in the GBM.
- **Membranous nephropathy (membranous glomerulonephritis)** membranous nephropathy is caused by subepithelial deposition of antibodies (IgG4 subclass) to antigens (M-type phospholipase A_2 receptor [PLA2R] protein) located on glomerular podocytes and activation of complement-mediated inflammation with injury and release of inflammatory mediators by mesangial and epithelial cells, resulting in increased membrane permeability, thickening of the glomerular membrane, and ultimately glomerular sclerosis.
- **Mesangial proliferative glomerulonephritis** deposition of immune complexes in the mesangium with mesangial cell proliferation and expansion reducing blood flow and altering filtration membrane permeability with development of hematuria, proteinuria, hypertension, and uremia (nephritic syndrome); associated with IgA nephropathy, lupus nephritis, or early diabetic nephropathy.
- **Rapidly progressive (crescentic) glomerulonephritis (RPGN) (subacute or extracapillary glomerulonephritis)** develops over days to weeks, primarily affects adults in their fifties and sixties, and may be idiopathic or associated with a proliferative glomerular disease (diffuse proliferation of extracapillary cells), such as lupus or poststreptococcal glomerulonephritis.

Glucose-6-phosphate dehydrogenase (G6PD) deficiency see Anemia.

Gluten-sensitive enteropathy (celiac sprue) a condition characterized by mucosal inflammation and villous atrophy in the gastrointestinal tract formed in response to a genetic predisposition for an immune response to gluten and similar proteins.

Gonorrhea a sexually transmitted disease caused by the bacteria gonococci that invade the mucous membranes of the genitals and urinary tract and in women the cervix, fallopian tubes, and ovaries, causing chronic pelvic pain or infertility.

Gout a disorder of uric acid metabolism that causes painful inflammation of the joints, commonly the big toe, and arthritic attacks resulting from elevated levels of uric acid in the blood and the deposition of negatively birefringent urate crystals around the joints.

Gouty arthritis inflammation of the joints in gout.

Graft rejection immunologic rejection of transplanted tissue or organs based on antigen differences between the donor and recipient.

- **Acute graft rejection** cell-mediated immune rejection that occurs within days to months after transplantation; immune response is usually against unmatched HLA antigens and develops after transplantation.
- **Chronic graft rejection** slow, progressive organ failure after a period of months or years of normal function by a developing weak cell-mediated immune response against minor histocompatibility antigens on the endothelial cells lining the blood vessels of the grafted tissue.
- **Hyperacute graft rejection** immediate rejection of a graft because of pre-existing antibodies against antigens expressed on the grafted tissue or organ.

Graft-versus-host disease (GVHD) condition in which mature T cells in a transplanted graft (e.g., transfused blood) are capable of a destructive cell-mediated reaction against unmatched histocompatibility antigens on the tissues in the graft recipient.

Granuloma inguinale a bacterial-induced disease, also called donovanosis, that is thought to be transmitted primarily by anal rather than vaginal intercourse and causes painless genital

ulcers like syphilis but progresses to destroy the internal and external genital tissue.

Graves disease autoimmune hyperthyroidism caused by antibodies that continuously activate TSH receptors, resulting in uncontrolled production of thyroxine and characterized by an enlarged thyroid gland, protrusion of eyeballs, a rapid heartbeat, and nervous excitability.

Guillain-Barré syndrome (GBS) (Landry-Guillain-Barré syndrome, idiopathic polyneuritis, acute inflammatory polyradiculopathy, acute autoimmune neuropathy) an acute, immune-mediated disorder of peripheral nerves, spinal roots, and cranial nerves that commonly presents as a rapidly progressive, areflexive, relatively symmetrical ascending weakness of the limb, truncal, respiratory, pharyngeal, and facial musculature, with variable sensory and autonomic dysfunction; typically reaches its peak activity within 2 to 3 weeks, followed by a plateau period of similar duration, and gradual but complete recovery in most cases; often preceded by a respiratory tract or gastrointestinal tract infection and is associated with albuminocytologic dissociation of the cerebrospinal fluid.

Guttate psoriasis see Psoriasis.

Gynecomastia abnormal breast tissue development on adolescent boys or men as a result of an imbalance in hormones.

Heat exhaustion occurs when sufficient salt and water loss results in hemoconcentration with hypotension occurring secondary to fluid loss (hypovolemia), and the individual feels weak, is nauseated, and can suddenly collapse.

Heat stroke a life-threatening condition associated with high environmental temperatures and humidity causing core body temperature to rise as a result of thermoregulatory failure.

Hematemesis accumulation of blood in the gastrointestinal tract causing irritation, increased peristalsis, and vomiting.

Hematochezia rapid bleeding from the upper GI tract producing bright red stools.

Hemochromatosis disorder of iron metabolism characterized by excessive absorption of ingested iron, saturation of iron-binding protein, and deposition of hemosiderin in tissue, particularly in the liver, pancreas, and skin; cirrhosis of the liver, diabetes (bronze diabetes), bronze pigmentation of the skin, and eventually heart failure may occur; also can result from administration of large amounts of iron orally, by injection, or in forms of blood transfusion therapy.

Hemoglobin H disease see Anemia.

Hemolytic anemia see Anemia.

Hemolytic disease of the newborn (HDN) (erythroblastosis fetalis) see Anemia.

Hemolytic jaundice (prehepatic jaundice, nonobstructive jaundice) jaundice resulting from excessive hemolysis of red blood cells.

Hemolytic-uremic syndrome (HUS) a condition in which platelets aggregate within the kidney's small blood vessels, resulting in reduced blood flow to the kidney and subsequent kidney failure and destruction of the red blood cells; occurs usually after exposure to Shiga-like toxin from a strain of *E. coli*.

Hemophilia A (classic hemophilia) a genetic disorder in which a mutation in factor VIII causes prolonged clotting time, decreased formation of thromboplastin, and diminished conversion of prothrombin.

Hemophilia B (Christmas disease) a genetic disorder similar to hemophilia A in terms of symptoms but with a mutation in the factor IX gene.

Hemophilia C (factor XI deficiency) a genetic disorder characterized by a deficiency in factor XI, resulting in a mild form of hemophilia.

Hemorrhagic stroke (spontaneous intracranial hemorrhage) stroke usually caused by hypertension that results in bleeding in the brain and typically increases intracranial pressure and may lead to death.

Henoch-Schönlein purpura nephritis inflammation of the blood vessels causing bleeding into the skin, mucous membranes, internal organs, and other tissues; pain and inflammation in the joints; abdominal pain; gastrointestinal bleeding; inflammation of the kidneys; subcutaneous edema; encephalopathy; and inflammation of the testis.

Heparin-induced thrombocytopenia (HIT) see Thrombocytopenia.

Hepatic encephalopathy a condition that is usually caused by liver cirrhosis and portal hypertension in which toxins produced by the gut pass into the systemic circulation and damage brain cells, resulting in impaired cognition, tremor, and a decreased level of consciousness.

Hepatocellular carcinoma (hepatocarcinoma; HCC) primary carcinoma of the liver developing in hepatocytes.

Hepatopulmonary syndrome intrapulmonary vasodilation, intrapulmonary shunting, and hypoxia and portopulmonary hypertension (pulmonary vasoconstriction and vascular remodeling) are common respiratory complications of advanced liver disease and portal hypertension.

Hepatorenal syndrome (HRS) acute renal failure occurs because of a decrease in renal blood flow secondary to liver disease.

Hereditary angioedema an inherited, autosomal dominant disease characterized by episodic appearance of nonpitting edema, most often affecting the limbs, but capable of involving other parts of the body, including mucosal surfaces such as those of the intestine (causing abdominal pain) or respiratory tract (causing asphyxia); associated with deficiency of inhibitor of the first component of complement pathway (C1 esterase inhibitor).

Hereditary hemochromatosis (HH) autosomal recessive chronic liver disease caused by excessive intestinal absorption of elemental iron; characterized by elevated serum iron saturation, transferrin, and ferritin levels; improves with phlebotomy; increased risk of developing cirrhosis, liver cancer, and liver failure.

Hereditary sideroblastic anemia see Anemia.

Hereditary spherocytosis see Anemia.

Hiatal hernia an anatomic abnormality in which the esophageal hiatus is larger than normal, causing part of the stomach to protrude through the diaphragm and up into the esophagus or chest.

High altitude cerebral edema (HACE) an increase in severity of symptoms or signs of neurologic dysfunction, such as ataxia or altered consciousness, related to high altitude.

High altitude pulmonary edema (HAPE) a noncardiogenic pulmonary edema associated with pulmonary hypertension and elevated capillary pressure related to high altitude illness.

Hirsutism abnormal growth and distribution of androgen-sensitive hair growth on the face, body, and pubic area in a male pattern that occurs in women.

Hodgkin lymphoma (HL) see Lymphoma.

Hormonal hyperplasia growth of cellular layers chiefly in estrogen-dependent organs, such as the uterus and breast. After ovulation, for example, estrogen stimulates the endometrium to grow and thicken for reception of the fertilized ovum.

Huntington disease (HD) an autosomal dominant disease causing a progressive increase in involuntary, jerky, dyskinetic movements; mental deterioration; and premature death.

Hyaline membrane disease (HMD) a type of respiratory distress syndrome of the newborn in which there is formation of a hyaline-like membrane lining the terminal respiratory passages; extensive atelectasis is attributed to lack of surfactant.

Hydrocephalus ex vacuo hydrocephalus attributable to loss or atrophy of brain tissue; less commonly associated with raised intracranial pressure and dilation of the cerebral ventricles.

Hydrops fetalis edema formation in the fetal subcutaneous tissue because of an enzyme deficiency or any one of several other disorders.

Hyperosmolar hyperglycemic nonketotic syndrome (HHNKS) a complication seen in diabetes mellitus in which very marked hyperglycemia occurs, causing osmotic shifts in water in brain cells, and resulting in coma. It can be fatal or lead to permanent neurologic damage.

Hypersensitive pneumonitis (extrinsic allergic alveolitis) an allergic, inflammatory disease of the lungs caused by inhalation of organic particles or fumes.

Hypertrophic cardiomyopathy a genetic disorder caused by various mutations that thicken the heart muscle, possibly leading to obstruction of blood flow and heart dysfunction; this is a common cause of sudden death in young athletes.

Hypogammaglobulinemia see Immune deficiency.

Hypoplastic anemia see Anemia.

Hypoplastic left heart syndrome (HLHS) a condition in which the left side of the heart, including the aorta, aortic valve, left ventricle, and mitral valve, is underdeveloped and blood returning from the lungs flows through an opening in the atrial septum and the right ventricle pumps the blood into the pulmonary artery and then into the aorta.

Hypospadias a birth defect in which the urethral opening is abnormally placed, opening

anywhere from the tip of the glans penis, to the shaft, or to the junction of the penis and scrotum or perineum in males; usually opens in the vagina in females.

Iatrogenic pneumothorax see Pneumothorax.

Icterus neonatorum (neonatal jaundice) jaundice in newborn infants caused by functional immaturity of the liver; usually subsides within the first few days of life.

Idiopathic pulmonary fibrosis (IPF) an excessive amount of fibrous or connective tissue in the lung.

Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura) see Thrombocytopenia.

IgA nephropathy (Berger disease) the most common form of idiopathic acute glomerulonephritis in developed countries, especially Asia; cause is unknown.

IgA pemphigus the most benign form of pemphigus characterized by tissue-bound and circulating IgA antibodies targeting desmosomal or nondesmosomal cell surface components in the basement membrane of the epidermis.

IgG subclass deficiency see Immune deficiency.

IL-7 receptor deficiency see Immune deficiency.

Immune deficiency a group of disorders in which one or more components of the immune or inflammatory response is impaired, resulting in increased susceptibility to infections. **Primary (congenital) immune deficiencies** result from genetic defects, and secondary immune deficiencies result from nongenetic factors, such as infections and other physiologic or pathophysiologic conditions. Primary immune deficiencies include:

- **B-lymphocyte deficiency** a group of disorders in which B-cell development is defective, resulting in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism. These include:
  - **Agammaglobulinemia** a condition in which no antibodies are produced.
  - **Autosomal agammaglobulinemia** an autosomal recessive form of agammaglobulinemia resulting from mutations in the B-cell receptor.
  - **Autosomal hyper-IgM syndrome** inability to class-switch resulting from mutations in CD40 on B cells.
  - **Bruton's agammaglobulinemia** a defect in B-cell development results in lower levels of circulating immunoglobulins and increased susceptibility to infections in which antibodies are the primary protective mechanism.
  - **Common variable immune deficiency** the most commonly diagnosed immune deficiency; hypogammaglobulinemia of IgG and other antibody classes; normal numbers of B cells, with or without associated T-cell defects.
  - **Hypogammaglobulinemia** a condition in which immunoglobulin levels are much lower than normal.
  - **IgG subclass deficiency** deficiencies in certain subclasses of antibody.
  - **Selective IgA deficiency** failure to produce IgA, with or without diminished production of other classes of antibody.
  - **X-linked hyper-IgM syndrome** inability to class-switch resulting from a defect in activation-induced cytidine deaminase (AICD).
- **Combined T- and B-lymphocyte deficiency** a group of immune deficiencies in which both T and B lymphocytes are defective. The most severe of these deficiencies is called **severe combined immune deficiency (SCID).** These include:
  - **Adenosine deaminase (ADA) deficiency** a form of SCID caused by an autosomal recessive mutation in the enzyme ADA, leading to death of rapidly dividing cells, particularly lymphocytes.
  - **Ataxia-telangiectasia (AT)** an autosomal recessive disorder resulting from a large variety of sporadic mutations in the *ATM* gene; often associated with ataxia (unsteady gait), telangiectasia (dilation of capillaries), and variable effects on both B and T cells.
  - **Bare lymphocyte syndrome** forms of SCID characterized by an inability of lymphocytes and macrophages to present antigen because of defects in class I (**MHC class I deficiency**) or class II (**MHC class II deficiency**) MHC antigen expression.
  - **IL-7 receptor deficiency** a form of SCID resulting from mutations in the IL-7 receptor, which is necessary for maturation of T cells.
  - **JAK3 deficiency** a form of SCID resulting from mutations in JAK3, which is an enzyme (a tyrosine kinase) associated with their receptor for IL-2.
  - **Purine nucleoside phosphorylase (PNP) deficiency** a form of SCID resulting from a mutation in the enzyme PNP.
  - **RAG-1 and RAG-2 deficiencies** autosomal recessive mutations in RAG-1 or RAG-2 enzyme that are necessary for genetic rearrangement of antibody and T-cell receptor variable regions.
  - **Reticular dysgenesis** the most severe form of SCID in which a common stem cell for all white blood cells is absent; therefore T cells, B cells, and phagocytic cells never develop.
  - **Wiskott-Aldrich syndrome (WAS)** an X-linked recessive trait resulting in chronic eczema with chronic suppurative otitis media, anemia, thrombocytopenic purpura, poor antibody response to polysaccharide antigens, and dysfunctions of cell-mediated immunity.
  - **X-linked SCID** a form of SCID with arrested maturation of T and NK cells and the production of immature B cells as a result of a defect in the IL-2 receptor gamma (γ)-chain (IL-2Rγ), which is shared with many other cytokine receptors.
- **Complement deficiency** a group of conditions in which specific proteins of the complement system are absent or suboptimal, resulting in diminished complement activity. These include:
  - **C1 deficiency** a deficiency of the first component of the classical pathway.
  - **C2 deficiency** a deficiency with an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).
  - **C3 deficiency** the most severe complement defect; an associated deficit of C3b, which is a major opsonin, results in a risk for recurrent life-threatening infections with encapsulated bacteria.
  - **C3 receptor deficiency** deficiencies in the complement receptor for C3 result in recurrent bacterial infections, particularly of the skin.
  - **C4 deficiency** results in an increased risk for recurrent respiratory tract infections with encapsulated bacteria and a systemic lupus erythematosus–like syndrome that may be complicated by kidney disease (glomerulonephritis).
  - **C9 deficiency** the most common terminal pathway defect and generally asymptomatic.
  - **Factor H deficiency** a deficiency of complement factor H resulting in increased destruction of C3 and a secondary C3 deficiency.
  - **Factor I deficiency** a deficiency of complement factor I resulting in increased destruction of C3 and a secondary C3 deficiency.
  - **Mannose-binding lectin (MBL) deficiency** a defect of the lectin pathway of complement activation resulting in an increased risk of infection with microorganisms that have polysaccharide capsules rich in mannose.
  - **Properdin deficiency** an X-linked defect in the alternative pathway of complement activation resulting in recurrent meningococcal infections.
- **Phagocytic deficiency** a group of conditions in which phagocytosis is diminished, resulting in increased bacterial infections. These include:
  - **Chediak-Higashi syndrome** a lethal, progressive, autosomal recessive, systemic disorder associated with oculocutaneous albinism, massive leukocyte inclusions (giant lysosomes), histiocytic infiltration of multiple body organs, development of pancytopenia, hepatosplenomegaly, and recurrent or persistent bacterial infections.
  - **Chronic granulomatous disease (CGD)** both X-linked and autosomal forms of mutations of the NADPH oxidase complex, resulting in diminished production of hydrogen peroxide and other oxygen products necessary for the bactericidal activity of myeloperoxidase.
  - **Cyclic neutropenia** an autosomal dominant mutation in the *ELA2* gene resulting in periods of neutropenia lasting a few days to weeks.

Severe congenital neutropenia inadequate numbers of neutrophils resulting in a variety of recurrent and severe bacterial infections beginning early in life.

Secondary immune deficiencies

Acquired immunodeficiency syndrome (AIDS) an epidemic, transmissible retroviral disease caused by infection with the human immunodeficiency virus (HIV), resulting in destruction of T-helper cells, suppression of both antibody and cellular immune responses, and development of life-threatening infections with opportunistic organisms.

Agranulocytosis complete absence of granulocytes in the blood is usually secondary to arrested hematopoiesis in the bone marrow or massive cell destruction in the circulation.

Qualitative leukocyte disorder a group of conditions with various disruptions of leukocyte function.

Quantitative leukocyte disorder a group of conditions, frequently associated with infections and leukemias, with decreased production of leukocytes in the bone marrow or accelerated destruction of leukocytes in the circulation.

Transient hypogammaglobulinemia of infancy a period at 6 to 8 months when the newborn may not have produced adequate amounts of antibody to replace maternal antibody; in some infants this may lead to a period of increased susceptibility to infections.

T-lymphocyte deficiency a group of disorders in which T-cell development is defective, resulting in lower levels of cellular immunity. Diminished T helper cell function may also decrease the production of antibody. These include:

Chronic mucocutaneous candidiasis a primary defect of T-lymphocyte response to a specific infectious agent, the yeast *C. albicans*.

DiGeorge syndrome a genetic disorder caused by deletion of a piece of chromosome 22 that results in cardiac defects, abnormal facies, thymic aplasia, cleft palate, and hypocalcemia.

Immune thrombocytopenic purpura (ITP) see Thrombocytopenia.

Imperforate anus a congenital defect in which the anal opening is absent because of the presence of a membranous septum or complete absence of the anal canal.

Impetigo a contagious bacterial infection that produces superficial red blisters that rupture and produce thick yellow crusts that commonly occur on the face but can spread to other regions of the body easily.

Infectious mononucleosis (IM) a disease caused by the Epstein-Barr virus or the cytomegalovirus that is transmitted by exchanging saliva or blood or by coughing and sneezing and acts by infecting the B cells and atypical T cells, resulting in fever, sore throat, and fatigue.

Infertility the inability to conceive after 1 year of unprotected intercourse with the same, opposite-sex partner.

Intracerebral hematoma (intraparenchymal hemorrhage) blood accumulation that partially clots inside the brain, usually in the frontal and temporal lobes.

Intraductal papilloma array of papillary cells that grow from the wall of a cyst into the lumen of the duct; growth occurs within a dilated duct often near or beside the nipple causing benign nipple discharge.

Intrarenal (intrinsic) acute kidney injury (AKI) a sudden decline in kidney function with a decrease in glomerular filtration and an accumulation of nitrogenous waste products in the blood (elevation in plasma creatinine and blood urea nitrogen levels); may result from ischemic acute tubular necrosis (ATN), nephrotoxic ATN (i.e., exposure to radiocontrast media or antibiotics), acute glomerulonephritis, vascular disease (malignant hypertension, disseminated intravascular coagulation, and renal vasculitis), allograft rejection, or interstitial disease (drug allergy, infection, tumor growth).

Invasive breast carcinoma a malignant invasive epithelial lesion derived from the terminal duct lobular area.

Invasive carcinoma of the cervix invasion of cervical carcinoma into adjacent tissues, such as ureters and structures of the lateral pelvic wall, the vaginal stroma and epithelium, and the lower uterine segment and myometrium.

Inverse psoriasis see Psoriasis.

Iron deficiency anemia (IDA) see Anemia.

Irritable bowel syndrome (IBS) a chronic noninflammatory disease with a psychophysiologic basis; characterized by abdominal pain, diarrhea or constipation, or both; no detectable pathologic change.

Irritative syndrome (radicular syndrome) a combination of changes usually seen with compromise of a spinal root within the intraspinal canal; these include neck or back pain and, in the affected root distribution, dermatomal pain, paresthesias, or both; decreased deep tendon reflexes; and occasionally myotomal weakness.

Isolated systolic hypertension loss of elasticity of the arteries resulting in an increase in cardiac output or stroke volume, a systolic blood pressure consistently greater than 160 mmHg, and a diastolic pressure less than 90 mmHg.

JAK3 deficiency see Immune deficiency.

Jaundice (icterus) yellowish brown staining of the skin and the conjunctivae caused by high bilirubin levels in blood secondary to excessive erythrocyte breakdown, obstruction in or around the liver, or liver disease.

Juvenile idiopathic arthritis (JIA) chronic pauciarticular arthritis and destruction of joints beginning in childhood and often going into remission at puberty.

Juvenile myoclonic epilepsy a type of epilepsy that occurs in adolescents and young adults, usually on awakening, and is characterized by jerks of the neck, shoulders, and arms and by clonic-tonic seizures.

Kaposi sarcoma (KS) a rare cancer of connective tissue caused by herpesvirus 8 (HHV8) in which many bluish red nodules appear on the skin, especially skin of the lower extremities; occurs in a particularly virulent form in individuals with AIDS.

Kawasaki disease a vascular disease characterized by an inflamed heart and vessels; a coronary artery aneurysm, thickening, and stenosis; a fever that lasts at least 5 days; and at least four of the following: inflammation with reddening of the whites of the eyes; red, swollen hands or feet or peeling skin; rash; swollen lymph glands in the neck; inflamed lips or throat; or red "strawberry" tongue.

Klinefelter syndrome smallness of testes with fibrosis and hyalinization of seminiferous tubules, variable degrees of masculinization, azoospermia, infertility, and increased levels of urinary gonadotropins; associated typically with an XXY chromosome complement although variants include XXYY, XXXY, and XXXXY.

Kwashiorkor a condition in which children do not receive enough protein in their diet, resulting in a swollen and severely bloated abdomen secondary to decreased albumin levels in the blood, skin changes resulting in a reddish discoloration of the hair and skin in dark-skinned children, severe diarrhea, fatty liver, muscle atrophy, and restricted development.

Lactase deficiency a condition in which insufficient lactase is present in the small intestine to digest lactose, resulting in lactose intolerance characterized by diarrhea, bloating, and gas in response to exposure to lactose.

Lactose intolerance a condition caused by lactase deficiency in which lactose is not metabolized, making it impossible for the small intestine to absorb it and causing excessive gas production and diarrhea when exposed to lactose-containing foods.

Lambert-Eaton myasthenic syndrome a generalized disorder of neuromuscular transmission caused by a defect in the release of acetylcholine from the presynaptic nerve terminals; often associated with small cell carcinoma of the lung, particularly in elderly men with a long history of cigarette smoking; weakness tends to affect solely axial muscles, girdle muscles, and less often the limb muscles; autonomic disturbances, dry mouth, and impotence are common; the deep tendon reflexes are unelicitable; caused by loss of voltage-sensitive calcium channels located on the presynaptic motor nerve terminal.

Laryngomalacia a congenital anomaly caused by a developmental delay in the laryngeal cartilage and supporting structures of the larynx that causes the cartilage to be floppy and fold in on itself during inspiration, producing high-pitched, coarse, and low-pitched sounds.

Left heart failure (congestive heart failure) inability of the left ventricle to maintain its circulatory load, with a corresponding rise in pressure in the pulmonary circulation usually with pulmonary congestion and ultimately pulmonary edema.

Legg-Calvé-Perthes disease blood supply to the head of the femur near the hip joint is

interrupted, resulting in osteonecrosis of the corresponding epiphysis.

Lennox-Gastaut syndrome a generalized myoclonic epilepsy that occurs in children between 1 and 5 years of age as a result of various cerebral afflictions such as perinatal hypoxia, hemorrhage, encephalitis, and metabolic disorders of the brain; it is characterized by mental retardation, personality disorders, and generalized tonic seizures.

Leukemia an acute or chronic malignant disease of the bone marrow and blood-forming organs; excessive proliferation of white blood cells occurs and is usually accompanied by dysfunctional blood cells, anemia, impaired blood clotting, and enlargement of the lymph nodes, liver, and spleen.

- **Acute leukemia** characterized by undifferentiated or immature cells, usually a blast cell, and the onset of disease is abrupt and rapid with a short survival time.
  - **Acute lymphoblastic/lymphocytic leukemia (ALL)** excessive production and continuous multiplication of malignant and immature white blood cells (lymphoblasts) in the bone marrow that progresses rapidly if left untreated.
  - **Acute myelogenous leukemia (AML)** excessive number of immature myeloid cells (myeloblasts) in the blood and bone marrow crowding out the marrow and decreasing the function of other cells.
- **Chronic leukemia** the predominant cell is more differentiated but does not function normally, with a relatively slow progression of the malignancy.
  - **Chronic lymphocytic leukemia (CLL)** malignant transformation and progressive accumulation in the marrow of monoclonal B lymphocytes; rarely are CLL malignancies of T-cell origin.
  - **Chronic myelogenous leukemia (CML)** production of heterogeneous myeloid cells in the bone marrow, the majority of which express the Philadelphia chromosome; CML is considered a myeloproliferative disorder.

LH deficiency a condition characterized by decreased or absent production of luteinizing hormone (LH), resulting in a decline in sex steroid production in testes/ovaries and associated infertility.

Lichen planus a recurrent rash of small, flat-topped bumps and rough scaly patches appearing on the skin, in the lining of the mouth, and in the vagina in response to inflammation or an allergy to a specific medication.

Localized scleroderma (morphea) rare and idiopathic sclerosis of the skin, usually with childhood onset.

Locked-in syndrome quadriplegia and mutism with intact consciousness and preservation of some eye movements; usually results from a vascular lesion of the anterior pons.

Lupus erythematosus any of a group of autoimmune connective tissue disorders that commonly produce red scaly lesions and are accompanied by fever, malaise, myalgias, fatigue, and weight loss.

- **Discoid (cutaneous) lupus erythematosus (DLE)** lupus erythematosus limited to the skin; can progress to systemic lupus erythematosus (SLE).
- **Systematic lupus erythematosus (SLE)** a chronic, multisystem, inflammatory disease; is one of the most common, complex, and serious of the autoimmune disorders.

Lyme disease (borreliosis) tick-borne spirochete bacterial infection that is characterized by a rash in the area of the bite, headache, neck stiffness, chills, fever, myalgia, arthralgia, malaise, fatigue, and possible development of arthritis in large joints.

Lymphoblastic lymphoma (LL) see Lymphoma.

Lymphogranuloma venereum (LGV) a sexually transmitted bacterial infection that enters the body through breaks in the skin or across the epithelial cell layer of mucous membranes and primarily targets the lymphatics and lymph nodes.

Lymphoma cancer arising from cell proliferation in lymphoid tissue.

- **B-cell neoplasm** a group of lymphomas including myelomas that originate from B cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.
- **Burkitt lymphoma** an aggressive malignancy of the B lymphocytes characterized by a large osteolytic lesion in the facial bones and associated with Epstein-Barr virus infection.
- **Hodgkin lymphoma (HL)** a cancer of lymphoid tissue in which the lymph nodes, spleen, and liver become enlarged with the presence of Reed-Sternberg cells and is often accompanied by anemia, fever, and eventually death if not treated at an early stage; also referred to as Hodgkin disease.
- **Lymphoblastic lymphoma (LL)** a progressive neoplasm arising in the thymus; most are of T-cell origin; a variant of acute lymphoblastic leukemia; common cause of NHL in children.
- **Lymphoplasmocytic lymphoma** also called Waldenström macroglobulinemia.
- **Mucosa-associated lymphoid tissue (MALT) lymphoma** a low-grade B-cell lymphoma linked to infection with *H. pylori.*
- **Mycosis fungoides** most common cutaneous T-cell lymphoma; present as focal or widespread erythematous patches or plaques, follicular papules, comedone-like lesions, and tumors.
- **NK-cell neoplasm** a group of lymphomas that originate from NK cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.
- **Non-Hodgkin lymphoma (NHL)** a group of malignancies of lymphoid tissue classified as B-cell, T-cell, and NK-cell lymphomas that mimic Hodgkin lymphoma but do not produce the cells characteristic of Hodgkin lymphoma; have been reclassified as B-cell, T-cell, or NK-cell neoplasms.
- **T-cell neoplasm** a variety of lymphomas that originate from T cells at various stages of differentiation; previously part of non-Hodgkin lymphoma.
- **Waldenström macroglobulinemia** a rare type of slow-growing plasma cell tumor that secretes a monoclonal IgM molecule; also called lymphoplasmocytic lymphoma.

Lymphoplasmocytic lymphoma see Lymphoma.

Lysosomal storage diseases a group of more than 30 disorders that result from impaired lysosomal function, leading to mucopolysaccharidoses, lipid storage disorders, mucolipidoses, leukodystrophies, and glycoprotein storage disorders.

Macrocytic anemia (megaloblastic anemia) see Anemia.

Major (unipolar) depression severely depressed mood and loss of pleasure that may begin suddenly or slowly; it persists for at least 2 weeks and may recur throughout life.

Malignant hyperthermia an inherited life-threatening disorder that causes muscle rigidity, a hypermetabolic state, tachycardia, and increased body temperature in response to administration of general anesthesics.

Malnutrition lack of nourishment from inadequate amounts of calories, protein, vitamins, or minerals; caused by improper diet, alterations in digestion or absorption, chronic disease, or a combination of these factors.

Mannose-binding lectin (MBL) deficiency see Immune deficiency.

Marasmus a childhood disorder characterized by protein and energy malnutrition, resulting in dry skin, loss of adipose tissue from normal areas of fat deposits such as buttocks and thighs, and behavior that is fretful and irritable.

Maturity-onset diabetes of youth (MODY) see Diabetes mellitis.

McArdle disease a metabolic disorder involving an enzyme defect that causes deficiency of muscle phosphorylase, which helps break down glycogen, and consequently this disorder causes an energy deficit in the muscles, resulting in muscle pain and cramping.

Meconium ileus obstruction with thickened meconium in the intestine of a newborn child as a result of a lack of trypsin and associated with cystic fibrosis of the pancreas.

Medulloblastoma a malignant cerebellar tumor near the fourth ventricle that is most often found in children and consists of neoplastic cells that resemble the undifferentiated cells of the neural tube.

Membranoproliferative glomerulonephritis (MPGN) see Glomerulonephritis.

Membranous glomerulonephritis see Glomerulonephritis.

Membranous nephropathy (membranous glomerulonephritis) see Glomerulonephritis.

Ménière disease (endolymphatic hydrops) dilation of the membranous labyrinth of the inner ear that is thought to be due to impaired absorption of endolymph in the endolymphatic sac; the pathologic finding in Ménière disease.

Ménière syndrome an affliction characterized clinically by vertigo, nausea, vomiting, tinnitus,

and fluctuating and progressive sensory hearing loss associated with endolymphatic hydrops.

Meningioma a slow-growing mass of the meninges that is usually benign but increases intracranial pressure

Meningocele neural tube defect in the skull or spinal column that forms a cyst filled with cerebrospinal fluid through which the meninges of the brain protrude.

Mesangial proliferative glomerulonephritis see Glomerulonephritis.

Mesenteric venous thrombosis a condition in which a blood clot obstructs one of the mesenteric veins and compromises the intestinal blood supply; can result in intestinal gangrene and tissue death.

Mesothelioma a type of cancer that is usually associated with previous exposure to asbestos, which affects the pleura, the lining of the abdominal cavity, the pericardium, and most internal organ coverings.

Metabolic syndrome a condition of unknown cause that presents with symptoms of insulin resistance, obesity, hypertension, dyslipidemia, and systemic inflammation.

Metatarsus adductus a foot deformity in which the front half of the foot bends inward, possibly because of the infant's position in the uterus.

MHC class I deficiency see Immune deficiency.

MHC class II deficiency see Immune deficiency.

Microcephaly defect in which failure of normal brain growth causes delayed skull growth and production of a small head.

Microcytic-hypochromic anemia see Anemia.

Microscopic colitis a relatively common cause of diarrhea; occurs primarily in females and older adults.

Migraine headache headache that usually begins in the temporal region unilaterally after vascular changes of cranial arteries and may cause irritability, nausea, vomiting, constipation or diarrhea, and photophobia.

Mild concussion (mild traumatic brain injury) temporary axonal disturbances without the loss of consciousness in response to a violent blow, jarring, shaking, or other closed-head injury.

Miliaria a skin disease caused by partially obstructed sweat glands that results in small and itchy rashes usually located in skinfolds and on areas of the body that may rub against clothing, such as the back, chest, and stomach.

Minimal change nephropathy (MCN) the foot processes of the renal capillary basement membrane are fused and deformed because of a T-cell disorder that reduces the anion component of the basement membrane and allows proteins to leak into the renal tubule.

Minimally conscious state (MCS) a condition in which a severely brain-damaged patient is capable of deliberate behavior distinguishable from unconscious reflexive actions.

Mitral valve prolapse syndrome the mitral valve cannot close properly because of one or both flaps being too large, possibly resulting in mitral valve regurgitation.

Mixed precocious puberty development of some secondary sex characteristics of the opposite sex (virilization of a girl or feminization of a boy); usually evident at birth and rare in older children.

Molluscum contagiosum a viral infection of the skin occurring in young children that affects the body, arms, and legs; it is spread through direct contact, saliva, or shared articles of clothing and is considered a sexually transmitted disease in adults, affecting the genitals, lower abdomen, buttocks, and inner thighs.

Monoclonal gammopathy of undetermined significance (MGUS) production of monoclonal antibodies by noncancerous plasma cells that accumulate in the blood.

Motility diarrhea diarrhea caused by excessive motility decreases transit time, mucosal surface contact, and fluid absorption secondary to resection of the small intestine (short bowel syndrome), surgical bypass of an area of the intestine, fistula formation between loops of intestine, irritable bowel syndrome–diarrhea predominant, diabetic neuropathy, hyperthyroidism, and laxative abuse.

Moyamoya disease an abnormality of the blood vessels that supply the frontal region of the brain in which vessels constrict or become completely occluded, resulting in diminished blood flow. The body attempts to compensate by growing new vessels at the base of the brain, which appear as a puff of smoke on angiography.

Mucoepidermoid carcinoma a tumor of the main or lobar bronchi lumen that may extend into the peribronchial tissue.

Mucolipidosis (ML) accumulations of both carbohydrates and lipids.

Mucopolysaccharidosis carbohydrate excess disorders.

Mucopurulent cervicitis (MPC) inflammation of the cervix with purulent endocervical exudate that may be asymptomatic or cause abnormal vaginal discharge and vaginal bleeding.

Mucosa-associated lymphoid tissue (MALT) lymphoma see Lymphoma.

Multiple myeloma (MM) most common and most aggressive plasma cell tumor; a clonal plasma cell cancer characterized by the slow proliferation of malignant cells as tumor cell masses in the bone marrow that usually results in destruction of the bone; most secrete large amounts of monoclonal proteins that resemble intact immunoglobulins.

Multiple organ dysfunction syndrome (MODS) progressive disease often involving the ultimate failure of two or more organ systems after a severe illness or injury; disease process is initiated and perpetuated by uncontrolled systemic inflammatory and stress responses and is characterized by a hypermetabolic and hyperdynamic state that persists as organ dysfunction develops.

Multiple papilloma (diffuse papillomatosis) a minimum of five papillomas within a localized segment of breast tissue.

Multiple sclerosis (MS) chronic demyelinating disease of the central nervous system that causes inflammation and scarring of myelin sheaths.

Muscular dystrophy a general term for a number of hereditary, progressive degenerative disorders affecting skeletal muscles, and often other organ systems.

Myasthenia gravis neuromuscular disorder caused by an autoimmune response in which antibodies to acetylcholine receptors impair neuromuscular transmission.

Mycosis fungoides see Lymphoma.

Myelodysplastic syndrome (MDS) a group of hematologic conditions characterized by ineffective production of blood cells, resulting in anemia that requires chronic blood transfusion.

Myoadenylate deaminase deficiency (MDD) a genetic disorder in which an enzyme deficiency prevents the conversion of adenosine monophosphate (AMP) to inosine monophosphate, resulting in increased AMP loss and the inability to synthesize adenosine triphosphate for energy.

Myocardial infarction a heart condition of sudden onset in which muscle tissue dies because of a lack of blood flow, resulting in varying degrees of chest pain or discomfort, weakness, sweating, nausea and vomiting, and possibly loss of consciousness.

Myositis inflammation of a muscle, usually a voluntary muscle, resulting in pain, tenderness, and sometimes spasm in the affected area.

Myositis ossificans a condition in which bone is deposited in muscle tissue, causing pain and swelling.

Myxedema cutaneous edema caused by deposition of connective tissue (e.g., glycosaminoglycans and hyaluronic acid) and associated with hypothyroidism and Graves disease; characterized by dry skin, pretibial myxedema, swelling around the lips and nose, mental deterioration, and a decrease in basal metabolic rate.

Necrotizing enterocolitis (NEC) a condition of extensive ulceration and necrosis of the ileum and colon in premature infants during the neonatal period.

Necrotizing fasciitis a rare, rapidly spreading inflammation starting in the fascia, muscles, and subcutaneous fat with subsequent necrosis of the overlying skin; it is initiated by bacterial infection and treated with antibiotics; often requires surgical débridement.

Neonatal alloimmune thrombocytopenic purpura (NATP) see Thrombocytopenia.

Neonatal purpura fulminans a fatal syndrome found in neonates who are homozygous or double heterozygous for types I and II protein deficiency.

Nephritic syndrome a disorder of the glomerular filtration membrane in which plasma proteins and red blood cells pass into the urine, resulting in mild proteinuria, hematuria, and mild hypertension.

Nephroblastoma (Wilms tumor) a malignant renal tumor of young children that compresses the normal kidney parenchyma, causing an abdominal mass, blood in the urine, and fever and may be associated with anorexia, vomiting, and malaise; often inherited as an autosomal dominant trait.

Nephrotic syndrome a disorder of the glomerular filtration membrane that permits proteins to pass into the urine, resulting in proteinuria,

hypoalbuminemia, hyperlipidemia, and systemic edema.

Neural tube defect (NTD) lack of closure of the neural groove caused by an arrest of the normal development of the brain and spinal cord during the first month of embryonic development.

Neuroblastoma a malignant tumor containing neuroblast cells that originate in the autonomic nervous system or the adrenal medulla; is most common in infants and young children.

Neurogenic shock (vasogenic shock) a type of shock caused by the sudden loss of the sympathetic nervous system signals to the smooth muscle in vessel walls, causing the vessels to relax and a decrease in peripheral vascular resistance and blood pressure.

Neuroleptic malignant syndrome hyperthermia with autonomic and extrapyramidal side effects caused by the administration of neuroleptic drugs.

NK-cell neoplasm see Lymphoma.

Nonalcoholic fatty liver disease (NAFLD) accumulation of fat in hepatocytes, primarily in the form of triglycerides, occurring in the absence of or with little alcohol intake; causes progressive inflammation and scarring that is usually asymptomatic for years.

Nonalcoholic steatohepatitis (NASH) a more serious form of nonalcoholic fatty liver disease resulting from hepatocellular injury, inflammation, and fibrosis; this condition is difficult to distinguish from alcohol-induced liver fibrosis; may progress to cirrhosis, end-stage liver disease, and an increased risk for hepatocellular carcinoma.

Nonbacterial infectious cystitis see Painful bladder syndrome/interstitial cystitis (PBS/IC).

Nonbacterial prostatitis prostatitis causes chronic pain that disappears and returns without warning but shows no signs of bacterial infection in the prostatic fluid even though the semen and other fluids from the prostate contain immune cells that the body produces in response to infection.

Non-Hodgkin lymphoma (NHL) see Lymphoma.

Noninfectious cystitis see Painful bladder syndrome/interstitial cystitis (PBS/IC).

Noninflammatory acne see Acne.

Noninflammatory joint disease a disease in which alterations in the structure or mechanics of the joint result in pain during motion.

Nonoliguric renal failure excretion of more than 500 ml/day of urine concurrent with renal failure; although adequate volume of urine is excreted, renal tubules have impaired reabsorption and concentration and dilution function so that filtration is defective, resulting in accumulation of uremic toxins in the blood.

Nonossifying fibroma (fibrous cortical deficit) a benign fibrous tissue tumor forms in the metaphysis of any of the long bones but usually occurs in the thigh and shin bones in children and adolescents.

Nonpuerperal hyperprolactinemia the presence of excessive amounts of prolactin (the pituitary hormone that stimulates milk production) in the blood not related to pregnancy or childbirth; most common cause of galactorrhea.

Nonsyndromic craniosynostosis (see Craniosynostosis) the premature closure of one or more of the cranial sutures during the first 18 to 20 months of an infant's life, but an isolated defect unrelated to syndrome.

Normocytic-normochromic anemia (NNA) see Anemia.

Obesity hypoventilation syndrome (pickwickian syndrome) a condition of severely overweight individuals related to the inability to breathe rapidly or deeply enough to maintain adequate blood oxygen levels; characterized by obstructive sleep apnea, somnolence, hypoventilation, erythrocytosis, and heart failure.

Obsessive-compulsive disorder (OCD) an anxiety disorder characterized by obsessive thoughts and repetitive compulsive actions, such as cleaning, checking, or counting.

Obstructive jaundice jaundice related to extrahepatic or intrahepatic obstruction.

Obstructive pulmonary disease airway obstruction that is worse with expiration so that more force or more time is required to expire a given volume of air and emptying of the lungs is slowed; characterized by shortness of breath (dyspnea) and wheezing.

Obstructive sleep apnea syndrome (OSAS) a disorder of sleep characterized by airway obstruction and episodes of apnea accompanied by snoring.

Obstructive uropathy the blockage of urine flow, often by ureteral or kidney stones, resulting in the reflux of urine and subsequent injury to kidneys.

Onychomycosis a fungal infection of the fingernails or toenails that causes thickening, roughness, and splitting of the nails.

Oophoritis inflammation of the ovaries.

Open pneumothorax (communicating pneumothorax) see Pneumothorax.

Optic glioma tumor originating from glial cells in the brain that affects the optic nerve; commonly seen in children with neurofibromatosis.

Organic brain syndrome a constellation of physical brain disorders with psychologic or behavioral signs and symptoms and grouped according to symptoms rather than etiology.

Orthopnea shortness of breath (dyspnea) that occurs when an individual lies flat and is common in individuals with heart failure.

Orthostatic (postural) hypotension a sudden drop in blood pressure when a person assumes a standing position, resulting in dizziness, lightheadedness, blurred vision, and temporary loss of consciousness.

Osmotic diarrhea nonabsorbable substance in the intestine draws water into the lumen by osmosis, resulting in large-volume diarrhea; caused by drinking solutions with excessive sugars, salt, or vitamin C; maldigestion syndromes.

Osteoarthritis (OA) inflammatory degenerative joint disease in which synthesis and degradation of the articular cartilage in the movable joints are altered, resulting in wearing and destruction of cartilage.

Osteochondrosis (Osgood-Schlatter disease) a condition in children that results from the tendons pulling on the epiphysis of long bones, causing pain just below the knee, irritation and swelling, and possibly abnormal bone growth.

Osteogenesis imperfecta (brittle bone disease) a genetic disease in which collagen production is deficient, making the bones abnormally fragile and causing recurring fractures with only minimal trauma, deformity of long bones, a bluish coloration of the sclerae, and often the development of otosclerosis.

Osteoid osteoma a benign tumor in one of the bones of the lower extremities that is painful and is characterized by vascularized connective tissue and osteoid material that is surrounded by a large zone of thickened bone.

Osteomalacia a disease in which vitamin D or calcium deficiency or excessive renal phosphate loss causes a softening of the bones with accompanying pain and weakness.

Osteomyelitis a bacterial infection of the bone and bone marrow that occurs through open fractures, penetrating wounds, surgical operations, or by infiltration of the bloodstream; causes pain, high fever, and formation of an abscess at the site of infection.

Osteoporosis a disease in which the bones become porous and weakened, making them easily fracture and slow to heal.

Overactive bladder syndrome (OAB) a chronic syndrome of overactivity of the detrusor muscle; characterized by urgency with involuntary detrusor contractions during the bladder filling phase.

Oxygen toxicity an iatrogenic inflammatory condition caused by prolonged exposure to high concentrations of supplemental oxygen resulting from damage to alveolocapillary membranes, disruption of surfactant production, and interstitial and alveolar edema; caused by oxygen free radicals.

Paget disease (osteitis deformans) a bone disorder in which excessive bone remodeling causes enlarged, deformed bones that can weaken the bone integrity and result in bone pain, arthritis, deformities, or fractures.

Painful bladder syndrome/interstitial cystitis (PBS/IC) (see Cystitis) a condition occurring in women ages 20 to 40 years who have symptoms of cystitis, such as frequency, urgency, dysuria, and nocturia, for more than 6 weeks duration; usually related to bacterial infection.

- **Nonbacterial infectious cystitis** cystitis with negative urine cultures and no other known etiology; most common in immunocompromised individuals and related to viral, mycobacterial, chlamydial, or fungal infection.
- **Noninfectious cystitis** cystitis without evidence of infection; usually autoimmune or related to exposure to radiation or chemotherapy treatment for pelvic or urogenital cancers.

Panacinar emphysema see Emphysema.

Pancreatic insufficiency a condition in which the pancreas does not secrete enough hormones and digestive enzymes for normal digestion to occur, resulting in malabsorption, malnutrition, vitamin deficiencies, and weight loss.

Pancreatitis inflammation of the pancreas, usually resulting in abdominal pain.

Panhypopituitarism a condition in which the secretion of all anterior pituitary hormones is inadequate or absent; caused by a variety of disorders that result in destruction or loss of function of all or most of the anterior pituitary gland.

Panic disorder a psychologic disorder that is characterized by recurrent attacks of anxiety or terror and usually results in the development of one or more phobias.

Papulosquamous disorder collective reference to inflammatory disorders characterized by papules, scales, plaques, and erythema, including psoriasis, pityriasis rosea, and lichen planus.

Paraesophageal hiatal hernia herniation of the greater curvature of the stomach through a secondary opening in the diaphragm.

Paraneoplastic pemphigus see Pemphigus.

Paraphimosis a condition in which the foreskin becomes trapped behind the glans penis and cannot return to its normal flaccid position covering the glans penis.

Parkinson disease degeneration of the basal ganglia dopaminergic nigrostriatal pathway that causes hypokinesia, tremor, and muscular rigidity.

Parkinsonism (Parkinson syndrome, parkinsonian syndrome) a neurologic condition characterized by tremors, rigidity, hypokinesia, and postural instability as a result of degeneration of the corpus striatum or substantia nigra caused by Parkinson disease and other conditions related to toxins or metabolic conditions.

Paroxysmal nocturnal dyspnea (PND) attacks of breathing discomfort, shortness of breath, and coughing that occur at night with varying intensity so that individuals must sit up or stand to relieve dyspnea; may occur in individuals with heart failure or lung disease.

Partial obstruction of the bladder outlet or urethra partial obstruction related to deposition of collagen within the smooth muscle bundles of the detrusor muscle; causes an increase in the force of detrusor contraction.

Partial precocious puberty the partial development of appropriate secondary sex characteristics alone or in combination.

Pediculosis pubis a contagious condition, also known as crabs or crab lice, that is an infestation of the pubic hair in which the louse feeds on human blood and multiplies rapidly.

Pelvic inflammatory disease (PID) inflammation of the female genital tract caused by microorganisms, typically those that are sexually transmitted such as chlamydia and gonococci; characterized by severe abdominal pain, high fever, vaginal discharge, and possibly infertility.

Pelvic organ prolapse (POP) bladder outlet obstruction in women caused most commonly by a cystocele (the downward protrusion of the bladder into the vagina) that descends below the level of the urethral outlet.

Pemphigus a group of autoimmune skin diseases marked by groups of itching blisters and raw sores on the skin and mucous membranes.

- **Paraneoplastic pemphigus** the most severe form of pemphigus; is associated with lymphoproliferative neoplasms and affects internal organs, including lungs, thyroid, kidney, smooth muscle, and gastrointestinal tract.
- **Pemphigus foliaceus** a milder form of pemphigus involving loss of cell-to-cell adhesion (acantholysis) at the subcorneal level with blistering, erosions, scaling, crusting, and erythema usually of the face and chest.
- **Pemphigus vulgaris** the most common form of pemphigus with acantholysis at the suprabasal level and initiated by IgG autoantibodies against the desmoglein adhesion molecules, resulting in acantholysis in the epidermis with fluid accumulation and blister formation; oral lesions precede the onset of skin blistering.

Pericarditis the pericardium is infected by a virus, bacteria, parasite, or fungus and becomes inflamed, resulting in pain and fluid and blood components entering into the pericardial space.

Perihepatitis (Fitz-Hugh–Curtis syndrome) a complication of pelvic inflammatory disease secondary to gonococci bacteria traveling up the peritoneum to the upper abdomen and causing inflammation.

Periodic paralysis one of a group of diseases in which muscular weakness or flaccid paralysis occurs without loss of consciousness, speech, or sensation.

Peripheral artery disease (PAD) any of a group of diseases caused by the obstruction of large peripheral arteries secondary to atherosclerosis, inflammatory processes, embolism, or thrombus formation that causes ischemia.

Pernicious anemia see Anemia.

Pes planus (flatfoot) a condition in which the arch of the foot never develops or it collapses and contacts the ground.

Peyronie disease (bent nail syndrome) a condition in which fibrous plaques grow in the soft tissue of the penis because of injury of the internal cavity of the penis that is accompanied by bleeding and scar tissue formation at the tunica albuginea of the corpora cavernosa.

Phagocytic deficiency see Immune deficiency.

Phenylketonuria (PKU) a genetic disorder in which the body lacks the enzyme necessary to metabolize the amino acid phenylalanine to tyrosine, resulting in accumulation of phenylalanine and subsequent brain damage and progressive mental retardation.

Pheochromocytoma a tumor of the adrenal medulla that causes the chromaffin cells to secrete increased amounts of epinephrine or norepinephrine.

Phimosis the foreskin of the penis of an uncircumcised male cannot be fully retracted.

Pick disease progressive atrophy of the cerebral convolutions in a limited area (lobe) of the brain, with clinical manifestations and course similar to those of Alzheimer disease.

Pityriasis rosea a skin disorder, thought to be caused by a virus, in which patches of ovular pink rash appear primarily on the trunk and extremities.

Plaque psoriasis see Psoriasis.

Pneumoconiosis a chronic disease of the lungs typically seen in miners, sandblasters, and metal grinders that is caused by repeated inhalation of dust particles, including iron oxides, silicates, and carbonates, that collect in the lungs and become sites for the formation of fibrous nodules that eventually replace lung tissue.

Pneumonia an infection of one or both lungs caused by a bacterium, virus, fungus, or other organism that enters the body through respiratory passages and causes high fever, chills, chest pain, difficulty breathing, cough with sputum, and possibly bluish skin from insufficiently oxygenated blood.

Pneumothorax the collapse of a lung and subsequent escape of air into the pleural cavity between the lung and the chest wall that is caused by trauma, environmental factors, or spontaneous occurrence and results in a sudden pain in the chest.

- **Iatrogenic pneumothorax** the presence of air or gas in the pleural space caused by a rupture in the visceral pleura (which surrounds the lungs) or the parietal pleura and chest wall; is most commonly caused by transthoracic needle aspiration.
- **Open pneumothorax (communicating pneumothorax)** spontaneous and traumatic pneumothorax in which air pressure in the pleural space equals barometric pressure because air that is drawn into the pleural space during inspiration (through the damaged chest wall and parietal pleura or through the lungs and damaged visceral pleura) is forced out during expiration.
- **Primary (spontaneous) pneumothorax** occurs unexpectedly in healthy individuals (usually men) between ages 20 and 40 years; is most often caused by the spontaneous rupture of blebs on the visceral pleura.
- **Secondary (traumatic) pneumothorax** spontaneous or secondary pneumothorax beginning with sudden pleural pain, tachypnea, and possibly mild dyspnea.
- **Tension pneumothorax** the site of pleural rupture acts as a one-way valve, permitting air to enter on inspiration, but preventing its escape by closing during expiration and leading to air pressure in the pneumothorax exceeding barometric pressure.

Polycystic ovary syndrome (PCOS) a hormonal condition in which multiple ovarian cysts form because of elevated levels of androgens, resulting in hirsutism, obesity, menstrual abnormalities, infertility, and enlarged ovaries.

Polycythemia vera a chronic, progressive disease that is characterized by overgrowth of the bone marrow, excessive red blood cell production, and an enlarged spleen and causes headache, inability to concentrate, and pain in the fingers and toes.

Pompe disease see Acid maltase disease.

Port-wine (nevus flammeus) stain a birthmark caused by superficial and deep dilated

capillaries in the skin that produce a reddish to purplish discoloration of the skin, usually on the face, but can occur anywhere on the body.

Postconcussive syndrome physical and personality changes that may occur after concussion of the brain, including amnesia, headache, dizziness, tinnitus, irritability, fatigability, sweating, heart palpitations, insomnia, and difficulty concentrating.

Posthemorrhagic anemia see Anemia.

Postobstructive pulmonary edema (POPE) (negative pressure pulmonary edema) a rare life-threatening complication that can occur after relief of upper airway obstruction (e.g., postextubation laryngospasm after anesthesia induction, epiglottitis, laryngeal tumor, or obstructive tonsils).

Postrenal acute kidney injury rare complication of urinary tract obstruction that affects the kidneys bilaterally (e.g., bilateral ureteral obstruction, bladder outlet obstruction–prostatic hypertrophy, tumors or neurogenic bladder, and urethral obstruction); obstruction causes an increase in intraluminal pressure upstream from the site of obstruction.

Post-thrombotic syndrome (PTS) a syndrome that follows a vascular thrombosis, such as persistent edema.

Posttraumatic stress disorder (PTSD) a psychologic disorder that may develop in individuals who have experienced or witnessed traumatic events; is characterized by recurrent flashbacks of the traumatic event, nightmares, irritability, anxiety, fatigue, forgetfulness, and social withdrawal.

Potter syndrome a syndrome of renal agenesis with hypoplastic lungs and associated neonatal respiratory distress, hemodynamic instability, acidosis, cyanosis, edema, and characteristic (Potter) facies; death usually occurs from respiratory insufficiency, which develops before uremia.

Poverty of content a disorder, also called poverty of speech content, that is characterized by disorganized speech that conveys little information and may be vague or contain repetitive or obscure phrases.

Prader-Willi syndrome a rare genetic disorder caused by gene deletions on paternal chromosome 15 that result in short stature, hypotonia, small hands and feet, obesity, mild to moderate mental retardation, and hypogonadism.

Precocious puberty a condition in which a boy or girl undergoes the changes associated with puberty at an unexpectedly early age; often caused by a pathologic process that increases the secretion of estrogens or androgens.

Premenstrual dysphoric disorder (PMDD) recurrence in the luteal phase of the menstrual cycle of distressing physical, psychologic, or behavioral changes that impair interpersonal relationships or interfere with usual activities.

Premenstrual syndrome (PMS) a group of symptoms that occur in many women from 2 to 14 days before menstruation begins, including abdominal bloating, breast tenderness, headache, fatigue, irritability, depression, and emotional distress.

Prerenal acute kidney injury rapid development of renal hypoperfusion with elevation of serum creatinine and urea levels.

Presbyopia a form of farsightedness usually accompanying advanced age in which the lens loses elasticity and becomes unable to accommodate and focus light for near vision.

Priapism a painful condition in which the erect penis maintains an erection in the absence of physical and psychologic stimulation.

Primary accidental hypothermia unintentional drop in core body temperature below 35° C (95° F) of a previously healthy person attributable to the changes that occur with cold temperatures.

Primary adrenal insufficiency (Addison disease) adrenal hypofunction resulting in bronzelike pigmentation of the skin, severe prostration, progressive anemia, low blood pressure, diarrhea, and digestive disturbance.

Primary amenorrhea continued absence of menarche and menstrual function by 14 years of age without the development of secondary sex characteristics or by age 16 years if these changes have occurred.

Primary biliary cirrhosis see Cirrhosis.

Primary (congenital) immune deficiency see Immune deficiency.

Primary dysmenorrhea painful menstruation because of a functional disturbance rather than because of inflammation, growths, or anatomic factors.

Primary gout acute episodes of urate crystal–induced synovitis resulting from abnormality of purine metabolism; lower-than-normal urinary excretion of urate leads to hyperuricemia and acute episodes of joint inflammation.

Primary hyperaldosteronism (Conn disease, primary aldosteronism) an adrenocortical disorder caused by excessive secretion of aldosterone and characterized by headaches, nocturia, polyuria, fatigue, hypertension, potassium depletion, hypokalemic alkalosis, hypervolemia, and decreased plasma renin activity; may be associated with small benign adrenocortical adenomas.

Primary hyperparathyroidism usually the result of a benign parathyroid tumor that secretes parathyroid hormone and increases circulating calcium levels; this condition is accompanied by hypercalcemia, nausea, vomiting, lethargy, depression, muscular weakness, and an altered mental state.

Primary hypertension (essential hypertension, idiopathic hypertension) elevated blood pressure of unknown etiology accompanied by increased total peripheral vascular resistance by vasoconstriction, increased cardiac output, or both.

Primary multiple organ dysfunction syndrome (MODS) multiple organ injury directly associated with a specific insult, most often ischemia or impaired perfusion from an episode of shock or trauma, thermal injury, soft tissue necrosis, or invasive infection with decreased local perfusion in the injured organs.

Primary (spontaneous) pneumothorax see Pneumothorax.

Primary syphilis a stage of syphilis infection that occurs after an incubation period of 10 to 90 days and is characterized by a primary sore or chancre that develops at the point of initial exposure and lasts 4 to 6 weeks.

Prinzmetal angina a form of angina pectoris characterized by pain that is not precipitated by cardiac work; it is of longer duration and usually more severe, and is associated with unusual electrocardiographic results including elevated ST segments.

Progressive bulbar palsy (see Bulbar palsy) a slowly progressive neurodegenerative disorder of the motor neurons of the cerebral cortex, spinal cord, and brainstem, resulting in progressive symptoms of bulbar palsy that may advance to loss of ability to manipulate food in the mouth, inability to swallow, choking, and emotional changes; may lead to aspiration of food and fluid and death from pneumonia.

Progressive spinal muscular atrophy a progressive degenerative disorder of the motor neurons of the spinal cord causing muscular weakness and wasting, typically beginning in the distal portions of the limbs and spreading proximally.

Prolactinoma the most common type of anterior pituitary tumor; produces visual disturbances and prolactin excess that results in infertility and changes in menstruation in females and impotence, loss of libido, and infertility in males.

Properdin deficiency see Immune deficiency.

Prostatitis inflammation of the prostate gland caused by urinary tract infection.

Protein C deficiency a disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa secondary to thrombosis, deep vein thrombosis, pulmonary embolism, thrombophlebitis, neonatal purpura fulminans, and disseminated intravascular coagulation.

Protein S deficiency a disorder characterized by a lack of anticoagulant activity and an increased tendency to form blood clots because of decreased degradation of factor Va and factor VIIIa.

Pseudothrombocytopenia see Thrombocytopenia.

Psoriasis a noncontagious autoimmune skin disorder in which the skin becomes scaly and inflamed when cells in the outer layer of skin reproduce faster than normal and accumulate as plaques on the skin surface.

- **Erythrodermic (exfoliative) psoriasis** widespread red, scaling lesions that cover a large body surface area; often accompanied by itching or pain associated with constitutional symptoms (fever, chills, fatigue) and skin infections.
- **Guttate psoriasis** sudden appearance of small papules on the trunk and extremities, occasionally after a streptococcal respiratory tract infection in children.
- **Inverse psoriasis** rare development of large, smooth, dry, and deep red lesions in skinfolds (i.e., axilla or groin).

Plaque psoriasis most common form of psoriasis; begins with well-demarcated, thick, silvery, scaly erythematosus inflammatory lesions with epidermal hyperproliferation and the presence of activated T lymphocytes that may become mild, moderate, or severe, depending on the size, distribution, and inflammation of the lesions.

Pustular psoriasis blisters of noninfectious pus that develop over areas of plaque psoriasis.

Pulmonary artery hypertension (PAH) increased blood pressure in the pulmonary artery attributable to vasoconstriction that may eventually lead to fibrosis, increased workload, hypertrophy of the right ventricle, and right heart failure; etiology may be idiopathic, familial, or associated with other diseases.

Pulmonary embolism (PE) dislodgement of a blood clot from its site of origin and embolization to the arterial blood supply of one of the lungs, resulting in shortness of breath and difficulty breathing, rapid breathing that is painful, cough, and (in severe cases) hypotension, shock, loss of consciousness, and death.

Pulmonary stenosis a condition in which the opening into the pulmonary artery from the right ventricle narrows.

Pure red cell aplasia (PRCA) an acquired or congenital condition in which the bone marrow lacks red blood cell precursors even though megakaryocytes and white blood cell precursors are usually present at normal levels.

Purine nucleoside phosphorylase (PNP) deficiency see Immune deficiency.

Pustular psoriasis see Psoriasis.

Pyloric stenosis a congenital abnormality in which the pylorus is narrow, resulting in poor feeding, weight loss, and progressively worsening vomiting.

Pyramidal/spastic cerebral palsy palsy resulting from damage or defects in the brain's corticospinal pathways (upper motor neuron) in either one or both hemispheres.

Qualitative leukocyte disorder see Immune deficiency.

Quantitative leukocyte disorder see Immune deficiency.

RAG-1/RAG-2 deficiencies see Immune deficiency.

Rapidly progressive (crescentic) glomerulonephritis (RPGN) see Glomerulonephritis.

Raynaud disease a condition in which the blood vessels spasm because of inadequate blood supply, resulting in discoloration of the fingers and/or toes after exposure to changes in temperature or emotional events.

Rectocele a condition caused by childbirth or hysterectomy in which the region between the rectum and vagina bulges toward the vagina, resulting in a sense of pressure or protrusion within the vagina, the feeling of incomplete emptying of the rectum, difficulty passing stool, discomfort or pain during evacuation or intercourse, constipation, vaginal bleeding, fecal incontinence, prolapse of the bulge through the opening of the vagina, or rectal prolapse through the anus.

Refeeding syndrome metabolic disturbances that occur upon initiating parenteral or enteral nutritional therapy to individuals who are severely malnourished; starvation results in movement of phosphate, magnesium, and potassium ions out of the cells and into the plasma and refeeding increases insulin levels and stimulates movement of glucose and these ions back into the cells, resulting in dangerously low levels in the plasma (hypophosphatemia, hypomagnesemia, hypokalemia, hyponatremia, hypocalcemia, and vitamin deficiency) and other potentially fatal metabolic complications.

Relative polycythemia a relative increase in the number of red blood cells caused by loss of the fluid portion of the blood.

Renal agenesis only one functional kidney is present at birth.

Renal dysplasia abnormal tissue development in one or both kidneys.

Respiratory distress syndrome (RDS) of the newborn a condition, also known as hyaline membrane disease (HMD), that is a type of respiratory distress in newborns, most often in prematurely born infants, those born by cesarean section, or those having a diabetic mother; the immature lungs do not produce enough surfactant to retain air so the air spaces empty completely and collapse after exhalation.

Reticular dysgenesis see Immune deficiency.

Retinoblastoma an autosomal dominant or sporadic disorder in which a malignant tumor forms in the retina of one or both eyes; typically found in infants.

Reversible sideroblastic anemia see Anemia.

Rhabdomyolysis a potentially fatal condition in which skeletal muscle breaks down as a result of injury such as physical damage to the muscle, high fever, metabolic disorders, excessive exertion, convulsions, or anoxia of the muscle for several hours; large amounts of myoglobin are usually excreted.

Rheumatic fever an inflammatory disease that is associated with recent streptococcal infection and causes inflammation of the joints, fever, jerky movements, nodules under the skin, and skin rash and often is followed by serious heart damage or disease secondary to antibodies that react both with streptococcal antigens and with those of the heart valve.

Rheumatic heart disease (RHD) sequela to rheumatic fever in which heart valves are repeatedly inflamed, developing fibrosis and thickening that can result in valve deformities, stenosis, or regurgitation.

Rheumatoid arthritis an autoimmune disease that causes chronic inflammation of the joints and the tissue around the joints and other organs.

Rickets a bone disease that is caused by a deficiency of vitamin D or calcium and manifests in children as softening of bones, abnormal growth of bones, and enlargement of cartilage at the ends of long bones.

Ringed sideroblast an erythroblast in which one third or more of the nucleus is encircled by 10 or more siderotic granules that may be caused by antituberculous drugs and alcohol abuse.

Roseola a viral disease in infants and young children that causes fever and a spotty rash that appears shortly after the fever has subsided.

Rotavirus a viral infection seen in young children that causes diarrhea by attacking the lining of the small intestine, resulting in the inability to absorb fluid and electrolytes.

Rubella an infectious viral disease of children and young adults that is spread by a droplet spray from the respiratory tract of an infected individual; the disease causes a rash that lasts about 3 days with tender and swollen lymph nodes behind the ears.

Rubeola an infectious viral disease of young children, also known as measles, that is spread by a droplet spray from the nose, mouth, and throat of individuals in the infective stage and causes a rash, white spots in the mouth, a rash on the face that spreads to the rest of the body, and fever.

Russell-Silver syndrome (Russell-Silver dwarfism) a growth disorder manifesting as retardation, proportionate short stature, leg length discrepancy, and a small, triangular-shaped face.

Saccular aneurysm (berry aneurysm) a localized, progressively growing sac that affects only a portion of the circumference of the arterial wall and may be the result of congenital anomalies or degeneration.

Saccular bronchiectasis (see Bronchiectasis) bronchiectasis resulting in dilated bronchi that become balloon-like.

Salmon patches (nevus simplex) patches, also known as stork bites, of small, pink, flat spots that are small dilated blood vessels visible through the skin and are usually found on the forehead, eyelids, and upper lip; between the eyebrows; and on the back of the neck.

Salpingitis inflammation of one of the two fallopian tubes caused by infection spreading from the vagina or uterus.

Sarcoma tumor of the connective tissue cells.

Scabies skin infestation with the itch mite, *Sarcoptes scabiei,* acquired through close contact with an infected person or contaminated clothing that produces intense itching.

Schizophrenia a psychotic disorder characterized by delusions, hallucinations, loosening of associations, disturbances in mood and sense of self and relationship to the external world, and bizarre, purposeless behavior.

Sclerosing adenosis a condition in which the number of acini per terminal duct is more than twice the number of normal terminal ducts and is associated with a significantly increased risk of subsequent breast carcinoma.

Scoliosis a condition in which the spine is curved sideways to varying degrees; occurs because of either physiologic curvature or functional curvature in which contraction of the paraspinal muscles of the back creates a vertebral curve.

Seborrheic dermatitis scaly, flaky, itchy, and red skin on the scalp, face, and trunk because of a yeast infection.

Seborrheic keratosis a benign proliferation of cutaneous basal cells that produces smooth or

warty elevated lesions; seen primarily in older people and presents as multiple lesions on the chest, back, and face.

Secondary (acquired) immune deficiency see Immune deficiency.

Secondary amenorrhea menstruation begins at puberty but then is subsequently suppressed for three or more cycles or for 6 months in women who previously menstruated.

Secondary dysmenorrhea altered menstruation because of inflammation, infection, tumor, or anatomic factors.

Secondary generalization the process by which a simple partial seizure involving one hemisphere becomes a generalized seizure involving the second hemisphere.

Secondary hyperparathyroidism a condition of elevated levels of parathyroid hormone resulting from disease such as renal failure in which parathyroid hormone concentration is elevated in response to vitamin D deficiency.

Secondary hypertension a condition of elevated blood pressure that is associated with other conditions, primarily with renal disease by a renin-dependent mechanism or a fluid volume–dependent mechanism.

Secondary hypothermia depressed body temperature as a consequence of a serious systemic disorder, for example, endocrine disorders.

Secondary MODS the result of an excessive inflammatory reaction, after a latent period following the initial injury, in organs distant from the site of the original injury. It is postulated that the resulting organ trauma is caused by the host response to a second insult rather than being a direct result of the primary injury.

Secondary (traumatic) pneumothorax see Pneumothorax.

Secondary septic arthritis a bacterial infection in the joints, causing them to become inflamed and the bacteria to proliferate.

Secondary syphilis the most contagious stage of syphilis infection; characterized by a skin rash that appears on the trunk and extremities 1 to 6 months after the primary infection and possibly mucous patches on the genitals or inside the mouth.

Selective IgA deficiency see Immune deficiency.

Septic shock a condition caused by systemic infection that results in decreased tissue perfusion and oxygenation and can lead to multiple organ dysfunction syndrome and death.

Serum sickness a form of hypersensitivity caused by injection of soluble antigen such as antiserum, which activates a type III hypersensitivity response (formation of soluble circulating antigen-antibody [IgG or IgM] complexes) that activates the complement system.

Severe combined immune deficiency (SCID) see Immune deficiency.

Severe congenital neutropenia see Immune deficiency.

Shock a condition in which the circulatory system is unable to provide adequate circulation to the body tissues because of inadequate pumping by the heart, a reduction in blood volume, or a reduction in blood pressure; it results in slowing of vital functions and possibly death.

Short bowel syndrome a group of malabsorption conditions resulting from massive resection of the small bowel, the degree and kind of malabsorption depending on the site and extent of the resection; it is characterized by diarrhea, steatorrhea, and malnutrition.

Sickle cell anemia see Anemia.

Sickle cell disease (SCD) see Anemia.

Sickle cell–Hb C disease see Anemia.

Sickle cell–thalassemia disease see Anemia.

Sickle cell trait see Anemia.

Sideroblastic anemia (SA) see Anemia.

Silicosis inflammation of the lung resulting from the inhalation of free silica (silicon dioxide) and silica-containing compounds, which occurs in mining and related industries.

Simple febrile seizure benign and most common form of childhood seizure.

Simple fibroadenoma benign solid tumors composed of both fibrous and glandular tissue.

Sliding hiatal hernia the most common type of hernia, occurring when the proximal portion of the stomach moves into the thoracic cavity through the esophageal hiatus, an opening in the diaphragm for the esophagus and vagus nerves.

Small cell lung carcinoma (SCLS) the most common type of neuroendocrine lung tumors and mostly arise from the central part of the lung.

Smallpox (variola) an infectious viral disease that is caused by a poxvirus and result in high fever, aches, and widespread eruption of large sores that leave scars.

Smoldering myeloma a condition in which abnormal plasma cells produce a monoclonal protein, but no symptoms or complications of myeloma are present and may not be present for several years.

Solitary plasmacytoma a solitary tumor of malignant plasma cells that may result in a single lytic bone lesion or may be in the tissues (extramedullary plasmacytoma).

Spina bifida occulta the mildest form of congenital disorder of incomplete closure of the embryonic neural tube; the outer part of some vertebrae may not be completely closed, but the defect is not apparent to the unaided eye and usually causes no serious neurologic dysfunctions.

Spinal stenosis narrowing of the spinal canal as a result of congenital anomaly or spinal degeneration, resulting in pain, paresthesias, and neurogenic claudication.

Spondylolisthesis forward displacement of one of the lower lumbar vertebrae over the vertebra below it or over the sacrum.

Squamous cell carcinoma (SCC) a tumor of the epidermis and the second most common human cancer.

Stable angina a condition in which ischemic attacks occur at predictable frequencies and duration after activities that increase myocardial oxygen demands such as exercise and stress.

Staphylococcal scalded-skin syndrome (SSSS) a disease in infants that is caused by a staphylococcal infection with release of an exfoliative toxin that results in peeling of large areas of skin.

Stevens-Johnson syndrome an inflammatory eruption of circular lesions that can cover the majority of the skin and mucous membranes and usually occurs after a respiratory tract infection or as an allergic reaction to drugs or other substances.

Strawberry hemangioma a red birthmark caused by densely packed blood vessels that usually appears on the face, scalp, back, and chest and disappears during childhood.

Stress ulcer acute peptic ulcer that occurs in association with various other pathologic conditions, including burns, cor pulmonale, intracranial lesions, and surgical operations.

Structural scoliosis a side-to-side curvature of the spine.

Subacute thyroiditis (subacute granulomatous thyroiditis, de Quervian thyroiditis) a painful inflammation of the thyroid that develops suddenly in a patient who has had a viral infection, such as mumps or an upper respiratory tract illness. Pain radiates throughout the neck and patients feel ill and feverish.

Subglottic stenosis narrowing of the airway below the larynx caused by a congenital anomaly or acquired narrowing secondary to injury, possibly resulting in respiratory distress, cyanotic episodes, or recurrent lung infections.

Sudden infant death syndrome (SIDS) a syndrome, also known as crib death, that is characterized by the sudden, unexpected, and unexplained death of an apparently healthy infant less than 1 year of age.

Superior vena cava syndrome (SVCS) restriction of the blood flow through the superior vena cava secondary to compression by malignancies or lymphadenopathy.

Sydenham chorea (St. Vitus dance) a postinfectious chorea appearing several months after a streptococcal infection with subsequent rheumatic fever. The chorea typically involves the distal limbs and is associated with hypotonia and emotional lability.

Symphysis fibrocartilaginous joint; a type of joint in which the apposed bony surfaces are firmly united by a plate of fibrocartilage.

Synchondrosis a cartilaginous joint creating a union between two immovable bones, such as the synchondroses of the cranium, the pubic symphysis, the sternum, and the manubrium.

Syndesmosis a fibrous union in which two bones are connected by interosseous ligaments, such as the anterior and the posterior ligaments in the radioulnar and tibiofibular articulations; is usually converted into bone before adult life.

Syndrome of inappropriate antidiuretic hormone (ADH) secretion (SIADH) a condition in which the release of ADH from the posterior pituitary is elevated relative to serum sodium levels, resulting in increased water reabsorption by the kidneys and fluid overload.

Syndromic craniosynostosis (see Craniosynostosis) synostosis that occurs as part of a genetic syndrome; usually associated with various dysmorphisms involving the face, skeleton, and nervous system and usually accompanied by developmental delay.

Syphilis a chronic infectious disease that is transmitted by direct contact, usually in sexual intercourse, or passed from mother to child in utero, and progresses through three stages characterized by chancres, ulcerous skin eruptions, and systemic infection that leads to damage to the cardiovascular and nervous systems.

Systemic inflammatory response syndrome (SIRS) a generalized inflammatory response that may lead to depressed cardiac function and decreased organ perfusion.

Systemic lupus erythematosus (SLE) (see Lupus erythematosus) a chronic, multisystem, inflammatory disease and one of the most common, complex, and serious of the autoimmune disorders.

Systolic heart failure a condition in which the heart muscle contracts so weakly that insufficient oxygenated blood is pumped throughout the body.

Tay-Sachs disease (GM2 gangliosidosis) a fatal autosomal recessive lysosomal storage disorder in which the lysosomal enzyme hexosaminidase A (HexA) is deficient, leading to accumulation of gangliosides in the brain and nerve tissue, mental retardation, convulsions, blindness, and premature death.

T-cell neoplasm see Lymphoma.

Tension pneumothorax see Pneumothorax.

Tertiary syphilis the most severe stage of syphilis, which can begin as early as 1 year after the initial infection but can take up to 10 years to manifest and is characterized by gummas—soft, tumor-like growths found in the skin and mucous membranes and often in the skeleton—joint deformity, neurosyphilis, and cardiovascular syphilis.

Tethered cord syndrome a group of neurologic disorders related to malformation of the spinal cord in which the cord becomes abnormally attached or tethered as a result of scar tissue that develops as the cord transcends the vertebral canal with growth; tethering may decrease blood flow.

Tetralogy of Fallot a congenital condition that is characterized by four malformations including ventricular septal defect, misplacement of the origin of the aorta, narrowing of the pulmonary artery, and enlargement of the right ventricle.

Thalassemia see Anemia.

Thromboangiitis obliterans (Buerger disease) inflammation of the medium-sized arteries and veins because of thrombotic occlusion, resulting in ischemia and gangrene.

Thrombocythemia a chronic disorder of sustained megakaryocyte proliferation that increases the number of circulating platelets and results in megakaryocytic hyperplasia, splenomegaly, and complications by hemorrhagic and thrombotic episodes.

Thrombocytopenia a reduced number of circulating platelets.

- **Acute idiopathic thrombotic thrombocytopenic purpura** a form of TTP characterized by thrombotic microangiopathy in which platelets aggregate and cause occlusion of arterioles and capillaries within the microcirculation, leading to increased platelet consumption and organ ischemia.
- **Autoimmune neonatal thrombocytopenia** destruction of platelets in a fetus/neonate by antiplatelet antibodies produced in the mother against her own platelet antigens (autoimmune) that are shared with the child, and the antibodies are transported across the placenta and destroy the child's platelets.
- **Chronic relapsing thrombotic thrombocytopenic purpura** a rare familial form of TTP characterized by recurring episodes of thrombocytopenia; usually seen in children.
- **Heparin-induced thrombocytopenia (HIT)** a form of drug-induced thrombocytopenia caused by IgG antibodies against the heparin–platelet factor 4 complex leading to platelet activation and thrombocytopenia.
- **Idiopathic thrombocytopenic purpura (ITP) (autoimmune or primary thrombocytopenic purpura)** the most common cause of thrombocytopenia, secondary to increased immune-mediated platelet destruction; can be acute or chronic.
- **Immune thrombocytopenic purpura (ITP)** a condition in which the number of platelets in the blood is reduced by the production of antibodies against platelets, resulting in ecchymoses and hemorrhages from mucous membranes, anemia, and extreme weakness.
- **Neonatal alloimmune thrombocytopenic purpura (NATP)** a condition in which fetal platelets have an antigen from the father that is absent in the mother, and the mother forms antibodies that cross the placenta and destroy the fetal platelets.
- **Pseudothrombocytopenia** an artificially low platelet count in anticoagulated blood caused by cooling of the blood and autoagglutination of platelets.
- **Thrombotic thrombocytopenic purpura (TTP)** altered blood coagulation caused by an enzymatic deficiency that is characterized by a reduced number of platelets in the blood, the formation of blood clots in tissue arterioles and capillaries, and neurologic damage.

Thrombophilia genetic or acquired abnormality of the coagulation system with an increased risk for thrombosis.

Thrombotic thrombocytopenic purpura (TTP) see Thrombocytopenia.

Thrush a yeast infection of the mouth and throat that presents as creamy white curd-like patches on the tongue, inside the mouth, and on the back of the throat and that is commonly associated with yeast infection of the esophagus.

Thyrotoxicosis excessive concentrations of thyroid hormones in the body that are marked by increased metabolic rate, heat intolerance, goiter, reproductive disorders, excessive sweating, and other alterations in systemic function.

Tinea capitis fungal infections of the skin classified according to their location on the body.

Tinea corporis (ringworm) a fungal infection of the scalp; much more common in children than adults.

Tinea infection one of a group of fungal skin infections that include athlete's foot, folliculitis, jock itch, ringworm, and pityriasis versicolor.

Tinea pedis chronic, superficial fungal infection of the skin of the foot common in adults.

Tinea unguium a fungal infection of the nails.

Tinnitus hearing ringing, buzzing, or other sounds without an external cause.

T-lymphocyte deficiency see Immune deficiency.

Tophaceous gout a form of purine metabolism disorder characterized by formation of chalky deposits of sodium biurate under the skin and in the joints.

Toxic epidermal necrolysis (TEN) a rare adverse reaction to certain drugs in which a large portion of the skin becomes intensely red, may develop blisters, and peels off.

Tracheomalacia (tracheobronchomalacia) a congenital or acquired condition characterized by weakness of the tracheal support cartilage, resulting in tracheal collapse when increased airflow is needed.

Trachoma (granular conjunctivitis or Egyptian ophthalmia) a contagious, chronic inflammation of the mucous membranes of the eyes, caused by *Chlamydia trachomatis*.

Transcortical dysphasia (transcortical sensory dysphasia, mixed transcortical dysphasia, isolated speech center) a type of aphasia with poor comprehension, but fluent grammatically correct speech. Patients can communicate well and are capable of good repetition.

Transient hypogammaglobulinemia of infancy see Immune deficiency.

Transient ischemic attach (TIA) brief episode in which the brain receives insufficient blood supply; symptoms depend on the site of the blockage.

Transposition of the great arteries (TGAs) the aorta arises from the right ventricle and the pulmonary artery arises from the left ventricle.

Traumatic (dissecting) aneurysm aneurysm caused by weakening of arterial walls, by a penetrating missile, or after neurosurgery or neuroimaging following an injury.

Trichomoniasis a sexually transmitted bacterial infection of the urethra in males and vagina in females that can cause urinary tract infection and a painful, malodorous vaginitis in women and urethral and bladder infection in males.

Tricuspid atresia congenital absence of the tricuspid orifice, circulation being made possible by the presence of an atrial septal defect.

True aneurysm localized dilation of an artery with an expanded lumen lined by stretched remnants of the arterial wall.

Truncus arteriosus a congenital defect in which a large great vessel arises from a ventricular septal defect and does not divide into the aorta and pulmonary artery, resulting in one vessel carrying blood both to the body and to the lungs.

TSH deficiency a condition characterized by decreased or absent production of thyroid-stimulating hormone (TSH), resulting in a decline in thyroid hormone level and subsequent symptoms such as fatigue, cold intolerance, weakness, depression, muscle aches, weight gain, and constipation.

Tuberculosis (TB) an infectious disease of humans caused by *Mycobacterium tuberculosis* that results in the formation of tubercles on the lungs and other tissues of the body.

Tuberous sclerosis complex (TSC) an inherited disease caused by mutation of the hamartin and tuberin genes and resulting in malformation of the brain, retina, and viscera and development of epileptic seizures, mental retardation, and skin nodules on the face.

Turner syndrome gonadal dysgenesis with short stature, undifferentiated (streak) gonads, and variable abnormalities such as webbing of the neck, low posterior hair line, increased carrying angle of elbow, cubitus valgus, and cardiac defects. The genotype is XO (45, X) or X/XX or X/XXX mosaic. The phenotype is female.

Type 1 diabetes mellitus see Diabetes.

Type 2 diabetes mellitus see Diabetes.

Ulcerative colitis chronically inflamed and ulcerated mucosal and submucosal lining of the large intestine, resulting in abdominal pain, diarrhea, and rectal bleeding.

Unclassified epileptic seizure seizure disorders that do not fit neatly into a classified grouping. These seizures characteristically have a wide variety of abnormal clinical activity. Examples of this activity include rhythmic eye movements, chewing, and swimming movements. These activities are commonly seen in neonatal seizures.

Undifferentiated large cell anaplastic cancer a cancer of epithelial origin that has lost all evidence of differentiation and may have arisen from a stem cell.

Unilateral neglect syndrome hemiapraxia with failure to pay attention to bodily grooming and stimuli on one side but not the other; usually caused by a lesion in the central nervous system.

Unstable angina a condition in which unprovoked ischemic attacks occur at unpredictable frequencies and may increase in severity.

Uremia syndrome of renal failure resulting in elevated blood urea and creatinine levels.

Uremic syndrome a complex of symptoms resulting from the accumulation of urea and other nitrogenous compounds and toxins in the blood, leading to alterations in levels of fluid and electrolytes, metabolic acidosis, anemia, hyperphosphatemia, and hypocalcemia; symptoms include hypertension, anorexia, nausea, vomiting, diarrhea or constipation, malnutrition and weight loss, pruritus, edema, anemia, and neurologic, cardiovascular disease, and skeletal changes.

Ureterohydronephrosis dilation of both the ureter and the pelvicaliceal system.

Ureteropelvic junction (UPJ) obstruction an impediment to the drainage of urine from the kidney, usually attributable to partial or intermittent blockage of the renal collecting system at the junction of the renal pelvis and ureter.

Urethral atresia congenital absence or closure of a normal body opening or tubular structure; congenital imperforation of the urethra.

Urothelial (transitional cell) carcinoma the most common bladder malignancy, appearing on the inner lining of the bladder.

Usual ductal hyperplasia (UDH) description of normal hyperplasia of cells that line the ducts in the normal breast; additional layers of benign cells are present, but with normal cellular structure and arrangement.

Uterine prolapse descent or herniation of the uterus into or beyond the vagina because of weakness of the pelvic musculature, ligaments, and fascia or obstetric trauma and lacerations sustained during labor and delivery.

Vacuolar myelopathy HIV-induced loss of myelin and spongy degeneration of the spinal cord that may cause spastic paraparesis, sensory ataxia in lower limbs, and unsteady gait.

Vaginismus a form of sexual dysfunction that is caused by a psychologic disorder or vaginal inflammation in which the muscles at the entrance to vagina contract and prevent sexual intercourse.

Vaginitis infection of the vagina usually caused by a fungus that may cause itching or burning and a discharge.

Vaginosis vaginal irritation without white blood cells or other indication of infection.

Varicocele a painful condition in which the veins in the scrotum that develop in the spermatic cord enlarge, and if the valves that regulate blood flow from these veins become dysfunctional, blood does not leave the testis, thereby causing swelling in the veins above and behind the testis.

Varicose bronchiectasis the bronchi become large and balloon-like.

Venous angioma abnormal veins, usually near the ventricular wall, that form as a congenital anomaly.

Venous stasis ulcer a condition affecting the lower leg in which leaky valves, obstructions, or regurgitation in veins impairs blood flow back to the heart, resulting in pooling of blood in the lower leg and subsequent tissue damage.

Ventricular septal defect (VSD) a congenital malformation in which the wall between the left and right ventricles has a hole that allows blood to travel between the left and right ventricles, potentially leading to congestive heart failure.

Vesicoureteral reflux (VUR) reflux of urine from the bladder into the ureter.

Vestibular nystagmus involuntary rapid movement of the eyeball that is due to disturbance of the vestibular system; eye movements are rhythmic, with slow and fast components.

Vitiligo an autoimmune-related loss of melanocytes resulting in the depigmentation of patches of skin.

von Willebrand disease an inherited disease in which the von Willebrand factor proteins that are made in the blood vessel walls and function to control platelet activity are abnormal or absent, resulting in a tendency to hemorrhage.

Waldenström macroglobulinemia see Lymphoma.

Wallerian degeneration the degeneration of a nerve fiber that has been separated from its nutritive center by injury or disease; characterized by segmentation of the myelin and resulting in atrophy and destruction of the axon.

Warm autoimmune hemolytic anemia see Anemia.

Wilms tumor see Nephroblastoma.

Wilson disease a genetic disease in which the ability to metabolize copper is impaired, resulting in an accumulation of copper deposits in organs such as the brain, liver, and kidneys and subsequent organ dysfunction and failure.

Wiskott-Aldrich syndrome (WAS) see Immune deficiency.

Xanthelasma a planar xanthoma involving the eyelid(s).

X-linked hyper-IgM syndrome see Immune deficiency.

X-linked SCID see Immune deficiency.

Zollinger-Ellison syndrome the association of atypical, intractable, sometimes fulminating peptic ulcers with extreme gastric hyperacidity and benign or malignant gastrinomas in the pancreas.

  croup caused by, 1294–1295
  description of, 317
  diseases caused by, 318t
  electron micrograph of, 317f
  infection from, 252, 303t
  intracellular survival of, 319
  invasion and evasion of, 319–320
  mechanisms of, to defend against inflammation and immunity, 308t
  neutralization of, 251f
  pathogenesis of, 320–322
  sexually transmitted infection caused by, 919t, 932–937
  type 1 diabetes mellitus and, 736b
Visceral endothelium, 1321–1322, 1324f
Visceral obesity, 1450
Visceral pain, 492, 1426
Visceral pericardium, 1085
Viscosity, blood flow and, 1112
Visfatin, secretion of, 1447b
Vision, 507–509
  aging effects on, 509–515
  dysfunction of, 509–513
  neurologic disorders and, 512–513
Visual acuity, alterations in, 510–511
Visual field, 509f
Visual pathway, 509f
Vital signs
  pediatric, 1702t
  pediatric shock and, 1701
Vitamin A, intestinal absorption of, 1406t
Vitamin A deficiency, 1440
Vitamin B
  DNA methylation and, 415–416
  intestinal absorption of, 1406t

Vitamin B_{12}
erythropoiesis requirements for, 962
replacement of, for pernicious anemia, 988–989
Vitamin B_{12} deficiency, pernicious anemia associated with, 987–988
Vitamin C, intestinal absorption of, 1406t
Vitamin D
bone and, 1512t
burn injury and, 1717
calcium balance and, 119–120
fracture risk and, 1556b
intestinal absorption of, 1406t
prostate cancer and, 902b
renal function affected by, 1334
role of, 703, 703b
Vitamin D_3, 1334, 1406t
Vitamin D deficiency, 703, 732, 1440
asthma associated with, 1308
chronic kidney disease and, 1368
nephrotic syndrome associated with, 1359, 1359t
osteomalacia associated with, 1557
rickets associated with, 1599–1600
Vitamin E
intestinal absorption of, 1406t
prostate cancer and, 902b
Vitamin E deficiency, 1440
Vitamin K
bone and, 1512t
coagulation and, 1042–1043
deficiency of, 1042–1043
Vitamin K deficiency, 1440
Vitamin(s)
cellular function and, 75
digestion and absorption of, 1405–1406, 1406t
erythropoiesis requirements for, 962
storage of, 1413
Vitiligo, 1617, 1620t–1622t
Vitreous humor, 508, 510t
Vitronectin, 305
Vivactil. *See* Protriptyline
VLDL. *See* Very-low-density lipoprotein (VLDL)
VO_2. *See* Oxygen consumption (VO_2)
Vocal cord, 1226–1228
carcinoma of, 1278
paralysis of, 1299
Vocal cord dysfunction (VCD), 1299
Vogt-Spielmeyer disease, 673t
Volatile acid, 123
Volkmann canal, 1517
Volume/pressure sensitive receptor, water balance and, 109
Voluntary muscle, 1526–1527
Volvulus
intestinal malrotation and, 1489
intestinal obstruction caused by, 1437t
Vomiting, 1424
brain dysfunction associated with, 533
gastroesophageal reflux disease as cause of, 1493–1494
gastrointestinal bleeding and, 1428
Vomiting *(Continued)*
intestinal obstruction as cause of, 1433–1434
pyloric obstruction associated with, 1430–1431
von Hippel-Lindau disease
childhood cancer associated with, 443t
congenital heart defects associated with, 1200t
von Recklinghausen disease, 154, 671t, 1200t
von Willebrand disease, 967, 1071
von Willebrand factor (vWF), 966–967
VS. *See* **Vegetative state (VS)**
VSD. *See* **Ventricular septal defect (VSD)**
VTE. *See* **Venous thromboembolism (VTE)**
Vulva, 771, 934f
Vulvar cancer, 829–830
Vulvitis, 816–817
Vulvodynia, 816–817
Vulvovaginal gland, 772
VUR. *See* **Vesicoureteral reflux (VUR)**
VWF. *See* Von Willebrand factor (vWF)
VZV. *See* **Varicella-zoster virus (VZV)**

W

Wakefulness, 502f
Waldenström macroglobulinemia, 1030, 1035
Wallerian degeneration, 450–451, 622
Wandering, description of, 563t
WAO. *See* World Allergy Organization (WAO)
Warburg effect, 370f, 420
Warfarin
congenital heart defects associated with, 1199, 1199t
thrombosis treated with, 1072
Warm autoimmune hemolytic anemia, 998
Warm shock, 1709
Warts, 1636–1637
Water
accumulation of, shock as cause of, 1670
balance of
alterations in, 109–114
chronic kidney disease and, 1366t
body
alternations in movement of, 105–108
balance of, 109
distribution of, 104t
excess of, 113–114
movement of, 105
normal gains and losses of, 104t
solute imbalances and, 110t
cell transport and, 28–33
cellular injury caused by, 84
small intestine transport of, 1401–1402
sodium and chloride balance and, 108–109
solute imbalances and, 110t
Water *(Continued)*
submersion in, injury caused by, 76, 76b
transport of, 33t
urine concentration and, 1332
Water deficit, 112
Water intoxication, 113–114
Water loss, burn injury and, 1691–1693
Water vapor, gas pressure and, 1237–1238
Watson, James, 136
WBC. *See* Leukocyte
WBI. *See* Whole-breast irradiation (WBI)
Weibel-Palade body, 966
Weight gain, breast cancer and, 860
Wellbutrin. *See* Bupropion
Wells syndrome, 1010–1011
Wernicke area, 457
Wernicke dysphasia, 543t–544t
West Nile virus, 318t
central nervous system diseases caused by, 610t
encephalitis caused by, 615b, 615t
West syndrome, 679–680
Western equine encephalitis virus, encephalitis caused by, 615t
Wet gangrene, 91
Wheal, example of, 1620t–1622t
Wheal and flare reaction, 272
Wheezing
asthma indicated by, 1309
description of, 1249–1250
foreign body aspiration as cause of, 1298
Whiplash, brain injury from, 587
White blood cell. *See* Leukocyte
White coat hypertension, 1220–1221
White fast-motor fiber, 1529
White graft, 280
White matter, 456–457, 461f
multiple sclerosis lesions in, 620
White muscle, 1529, 1530t
White stroke, 599
Whole-breast irradiation (WBI), 857
Whole-breast radiation therapy, 857
Whooping cough, 304t–305t
Wickham striae, 1630–1631
Wilms tumor, 188, 1385–1386
childhood cancer associated with, 444
clinical manifestations of, 1386
evaluation and treatment of, 1386
inheritance of, 379–380
pathogenesis of, 1385–1386
staging of, 1386t
survival rates for, 1386t
Wilms tumor 1 *(WT1)* gene, 1376
Wilson disease, 673t, 1503t, 1504–1506
Windchill factor, 497
Window period, infection and, 327
Wingless type signaling, urinary tract development and, 1376
Wireless telephone, radiation exposure from, 432
Wirsung duct, 1413
Wiskott-Aldrich syndrome, 281, 283f, 286–287
acute leukemia associated with, 1017
childhood cancer associated with, 443t
Wnt gene, 1512
Wnt signaling, 1376, 1553
Wolff-Parkinson-White syndrome, pathophysiology and treatment of, 1184t–1186t
Wolff's law, 1515
Work of breathing, 1236–1237
Working memory, 538, 643
Working memory deficit, 538, 541t
World Allergy Organization (WAO), 1675, 1675b
World Health Organization (WHO), smallpox immunization campaign from, 332
Wound
infection of, bacteria as cause of, 304t–305t
resolution and repair of, 215–220, 217f
sepsis in, 218
Wound contraction, 218
Wound healing, 215–220
abnormal, skin lesion associated with, 1626
bone, 1520
burn, 1722, 1722b
diabetes mellitus and, 752
disruption of, 220
dysfunctional, 218–220
Treg cell and, 386–387
tumor growth and, 385f
Wound infection, *Staphylococcus aureus* associated with, 311f
Wound repair, myocardial infarction and, 1160
Woven bone, 1520
Wrist, dislocation or subluxation of, 1544
Wuchereria bancrofti, 314t, 316

X

X chromosome, 156
X descent, 1089–1090
X inactivation, 156–157
X-linked agammaglobulinemia, 284, 1017
X-linked hyper-IgM syndrome, 284
X-linked inheritance, 156–158
X-linked lymphoproliferative syndrome, 1013
X-linked recessive gene, 158
X-linked severe combined immune deficiency, 286
X-ray
breast cancer associated with, 856
chest, 1119
ionizing radiation from, 78–80
of skull and spine, 477–478
Xanthelasma, 1154
Xanthine dehydrogenase, 1683
Xanthine oxidase, 1683
Xanthine stone, 1344
Xanthoma, 174f
Xenobiotics, 416–417
Xenoestrogen, breast cancer and, 861
Xeroderma pigmentosum, 379

Y

Y chromosome, 157
Y descent, 1089–1090
Yawning, brain dysfunction associated with, 533
Yeast, 310–311, 312f
Yellow fever virus, 318t

Yellow marrow, 1518
Yersinia pestis, 304t–305t
Yersinia spp., 306–307
Young adult
  cancer incidence in, 442
  seizures in, 554t

Z

Z line, 1098–1099
Zellweger encephalopathy, 673t
Zinc, immune system affected by level of, 291
Ziprasidone, schizophrenia treated with, 646b, 647
Zollinger-Ellison syndrome, 1438
Zoloft. *See* Sertraline
Zona fasciculata, 706
Zona glomerulosa, 706
Zona reticularis, 706
Zoonotic infection
  bacteria associated with, 304t–305t
  viral, 317
Zygote, chromosomal deletion and, 148–149
Zyprexa. *See* Olanzapine

COMMON LABORATORY VALUES*

CONSTITUENT	NORMAL MEAN VALUE AND SOME RANGES	NORMAL RANGE IN SI UNITS
Electrolytes	Total, 1% of plasma weight	
Na^+	135-145 mEq/L	135-145 mmol/L
K^+	3.5-5.0 mEq/L	3.5-5.0 mmol/L
Ca^{++} (serum)	8.4-10.6 mg/dl	2.10-2.65 mmol/L
Mg^{++}	1.3-2.1 mg/dl	0.65-1.05 mmol/L
Cl^-	96-106 mEq/L	96-106 mmol/L
HCO_3^- (venous)	23-29 mEq/L	23-29 mmol/L
Phosphate (mostly HPO_4^-)	3.0-4.5 mg/L	1.0-1.5 mmol/L
SO_4^-	1 mEq/L	0.25-0.75 mmol/L
Proteins	6-8 g/dl	60-80 g/L
Albumin	3.3-5.5 g/dl	33-55 g/L
Gamma globulin	0.7-1.7 g/dl	7-17 g/L
Globulins	2-4 g/dl	20-40 g/L
Fibrinogen	200-400 mg/dl	2-4 g/L
Troponin I	0.05-0.50 ng/ml	0.05-0.50 ng/ml
Blood Gases		
pH (arterial)	7.35-7.45	7.35-7.45
CO_2 content (arterial)	35-45 mm Hg	35-45 mm Hg
O_2 content (arterial)	80-100 mm Hg	80-100 mm Hg
Bicarbonate (arterial)	21-27 mEq/L	21-27 mmol/L
Nutrients		
Glucose (fasting)	75-110 mg/dl	3.85-6.05 nmol/L
Total proteins	6-8 g/dl	—
Total lipids	400-800 mg/dl	4.0-8.0 g/L
Cholesterol (total)	<200 mg/dl	<5.20 mmol/L
Triglycerides (after 12 hr fast)	<150 mg/dl	0.45-1.81 mmol/L (males) 0.40-1.52 mmol/L (females)
Phospholipids	150-380 mg/dl	1.50-3.80 mol/L
Free fatty acids	9.0-15.0 mM/L	9.0-15.0 mM/L
Waste Products		
Urea (BUN)	24-49 mg/dl	4.0-8.2 nmol/L
Uric acid (serum)	2.2-8.0 mg/dl	130-476 μmol/L
Creatinine	0.6-1.2 mg/dl	53-106 μmol/L
Creatinine clearance	107-139 ml/min	1.78-2.32 mmol/L
Bilirubin (conjugated)	0.1-0.4 mg/dl	1.7-6.8 μmol/L
Bilirubin (total)	0.3-1.1 mg/dl	5.1-19.0 μmol/L
Individual Hormones		
Prolactin	<20 ng/ml	<20 μg/L
Thyroid tests		
Thyroxine (T_4)	4-11 μg/mL	58-154 nmol/L
T_4 expressed as iodine	3.2-7.2 ng/dl	253-569 nmol/L
T_3	75-220 ng/dl	975 nmol/L
Free thyroxine (T_4)	0.9-2.1 ng/dl	12-27 pmol/L
T_3 resin uptake	25%-38%	0.25-0.38
TSH	0.4-4.8 μIU/mL	0.4-4.8 μIU/L
Hematology Values		
Erythrocyte (red blood cell count)	4.2-6.2 million/mm^3	$4.2–6.2 \times 10^{12}$/L
Leukocyte (white blood cell count)	4500-11,000/mm^3	$4.5-11.2 \times 10^9$/L
Lymphocyte	25%-33% of leukocyte differential	$1500–3000 \times 10^6$/L

COMMON LABORATORY VALUES—cont'd

CONSTITUENT	NORMAL MEAN VALUE AND SOME RANGES	NORMAL RANGE IN SI UNITS
Monocyte and macrophage	3%-7% of leukocyte differential	300–500 × 10^6/L
Eosinophil	1%-3% of leukocyte differential	50–250 × 10^6/L
Neutrophil (segmented)	54%-62% of leukocyte differential	3000–5800 × 10^6/L
Basophil	0-1% of leukocyte differential	15–50 × 10^6/L
Platelet	150,000-400,000/mm^3	150–400 × 10^9/L
Hematocrit	37%-54%	0.40–0.54 g/L
Hemoglobin	12-18.0 g/dl	7.4–11.2 mmol/L
Mean corpuscular volume	80–96 mcm^3	80–96 fL
Hemoglobin A_{1c}	3–5% of total	0.03–0.05 of total
Serum Enzymes		
Lactic dehydrogenase	110-220 units/L	110-220 units/L
Isoenzymes:		
LDH-1 (heart)	17% to 27%	
LDH-2 (reticuloendothelial system)	27% to 37%	
LDH-3 (lungs)	18% to 25%	
LDH-4 (kidney, placenta, pancreas)	3% to 8%	
LDH-5 (liver, striated muscle)	0% to 5%	
Phosphatase P acid (units/Ll)	Cherry-Crandall	0.1-0.6 units/L
	King-Armstrong	0.1-0.6 units/L
	Bodansky	0.1-0.6 units/L
Alkaline Phosphatase (units/L)	King-Armstrong	35-150 units/L
	Bodansky	35-150 units/L
	Bessey-Lowry-Brock	35-150 units/L
Aspartate aminotransferase (AST; previously serum glutamate oxaloacetate transaminase [SGOT])		
Female	6-34 units/L	6-34 units/L
Male	8-40 units/L	8-40 units/L
Alanine aminotransferase (AST; previously serum glutamate oxaloacetate transaminase [SGOT])		
Female	9-32 units/L	9-32 units/L
Male	10-40 units/L	10-40 units/L
Creatine kinase		
Female	30-135 units/L	30-135 units/L
Male	55-170 units/L	55-170 units/L
Amylase	25-125 units/L	25-125 units/L
Lipase	10-140 units/L	10-140 units/L
Other		
Bile acids	0.3-3.0 mg/dl	0.8-7.6 mmol/L
Bilirubin, direct (conjugated)	0.1- 0.4 mg/dl	1.7-6.8 μmol/L
Bilirubin, indirect (unconjugated)	0.1-1.0 mg/dl	1.7-17.1 μmol/L
Creatine (s)	0.2-0.9mg/dl	15-70 μmol/L
Creatinine	0.6-1.2 mg/dl	50-110 μmol/L
Iron, total (s)	60-150 μg/dl	11-27 μmol/L
Iron-binding capacity (s)	300-360 μg/dl	54-64 μmol/L
Phosphorus, inorganic (s)	3.0-4.5 mg/dl	0.97-1.45 mmol/L
Prothrombin time	10-13 seconds	
Partial thromboplastin time	22-37 seconds	
Erythrocyte sedimentation rate (ESR or sed rate)		
Westergren method		
Men under 50 years	<15 mm/hr	
Men over 50 years	<20 mm/hr	
Women under 50 years	<20 mm/hr	
Men under 50 years	<30 mm/hr	

*Note: Reference ranges may vary because of differences in laboratory methods and modes of instrument standardization. Above reference values are from *Dorland's illustrated medical dictionary,* ed 32, Philadelphia, Saunders, 2012; *SI;* International System of Units.
